Small clitoral size is found in patients with complete androgen insensitivity syndrome (CAIS) (Fig. 149-4). One study evaluating 19 patients with known CAIS revealed a statistically significantly reduced mean clitoral length compared to that in controls (Crouch et al, 2011). In contrast, no difference was observed for the clitoral to urethral distance between the two groups.

Figure 149-4. Diminutive clitoris in complete androgen insensitivity syndrome.

Disorders of the Vestibule

Urethral Prolapse

Urethral prolapse generally involves complete circumferential eversion of the urethral mucosa at the level of the external urethral meatus (Fig. 149-5) (Lowe et al, 1986). This entity, which was first described by Solinger in 1732, occurs most often in prepubertal black girls and in postmenopausal white women (Epstein and Strauss, 1937; Richardson et al, 1982). Various causes that have been proposed for urethral prolapse include hypoestrogenism (Desai and Cohen, 1997), abnormal connections between the inner longitudinal and outer circular muscle layers of the distal urethra (Lowe et al, 1986), and episodic increases in intra-abdominal pressure (Lowe et al, 1986; Desai and Cohen, 1997; Valerie et al, 1999). The most common initial complaint is bleeding from the edematous and friable mucosa, which results in blood spotting on the underwear (Richardson et al, 1982; Chaouachi et al, 1989). Urethral prolapse is easily recognized as a doughnut-shaped mass with the urethral meatus at the center. If the diagnosis can be confirmed by passing a urethral catheter, radiographic evaluation is not indicated (Nussbaum and Lebowitz, 1983). Treatment options include observation, topical corticosteroids, and surgical excision (Redman, 1982; Fernandes et al, 1993). Sitz baths may be helpful. Nonoperative treatment may lead to spontaneous reduction of the prolapse, but a recurrence rate of up to 67% has been noted (Jerkins et al, 1984). Many methods of surgical repair have been described. Circumferential excision of the redundant mucosa with subsequent suturing of the normal urethra to the vestibule is the procedure of choice (Devine and Kessel, 1980). Other methods, including ligation over a transurethral catheter with subsequent sloughing and cryosurgery, should be discouraged (Owens and Morse, 1968; Klaus and Stein, 1973).

Urethral Polyp

The pediatric equivalent of a urethral caruncle, namely, a urethral polyp, is a rare lesion that can manifest as an interlabial mass (Fig. 149-6). The cause of these lesions has not been completely elucidated, but in a young child they probably represent either hamartomatous growth or a response to inflammation.

We described two young girls with an interlabial mass. Histologic examination of each excised mass revealed a benign urethral polyp covered with transitional and squamous epithelium (Klee et al, 1993). Urethral polyps should be included in the differential diagnosis of an interlabial mass in young female patients.

Vestibular Cysts

Introital cysts in the newborn can represent one of three entities: paraurethral cysts (i.e., Skene duct cyst), remnants of the mesonephric

ductal system (Gartner duct cyst), and a covered ectopic ureter. When the cyst is large and clearly emanating from the vaginal introitus, further investigation in the form of a renal-pelvic ultrasound evaluation is indicated to look for renal duplication.

Paraurethral cysts in a neonate represent a dilation of the periurethral glands, which are located just inside the urethral meatus (Fig. 149-7). These glands are homologs of the male prostatic

Figure 149-8. Retrograde injection of an ectopic ureter inserting into a Gartner duct cyst. After injection of a vaginal cyst, contrast agent ascends cranially into an atretic, dysplastic ureter.

glands and number between 6 and 30, with the two largest termed the *periurethral glands of Skene* (Skene, 1880; Gottesman and Sparkuhl, 1979). In a neonate the periurethral glands occasionally respond to maternal estrogen and secrete mucoid material, which can result in cyst formation. The main distinguishing feature of this condition is displacement of the urethral meatus by the mass and, consequently, an eccentric urinary stream. If the urethral meatus can be identified as being completely separate from the mass, radiographic evaluation is not needed to confirm the diagnosis (Nussbaum and Lebowitz, 1983). These cysts are frequently self-limited and often rupture spontaneously. If they are persistent, drainage by a small needle is easily achieved at the bedside.

Gartner duct cysts represent cystic remnants of the wolffian duct system and can be found along the anteromedial wall of the vagina (Pradhan and Tobon, 1986). A cystic structure related to a Gartner duct cyst is a covered ectopic ureter that enters into the vagina (Rosenfeld and Lis, 1993; Holmes et al, 1999). Embryologically, the ureter would not be expected to enter the vagina. However, an ectopically located ureter may end in a segment of the wolffian duct system, which in a female is represented by a Gartner duct cyst. In most instances this cystic structure spontaneously ruptures before delivery, thereby resulting in direct communication between the ectopic ureter and the vagina. However, if the surface epithelium fails to rupture, a covered, urine-filled cyst will exist within the vagina. Intraoperative injection of the cystic structure with radiographic contrast material may be beneficial in outlining the anatomy (Fig. 149-8). Incision of the cystic structure relieves the obstruction. As a general rule, the more ectopic the insertion of the ureter, the more dysplastic will be the segment that it drains. However, renal moieties that ectopically insert into the vagina may produce urine. Subsequent upper pole heminephrectomy may be indicated if the child has significant urine production from the segment (resulting in incontinence) or an infection develops after decompression.

Prolapsed Ureterocele

An ectopic ureterocele is a cystic dilation of the terminal portion of the ureter that occurs predominantly in white females (Mandell et al, 1980). Approximately 90% of ectopic ureteroceles are associated with the upper pole of a duplex collecting system. Although

Figure 149-9. A, Prolapsed ureterocele. B, Prolapsed ureterocele with catheter inserted in the urethra.

Figure 149-11. Ectopic ureter to vestibule.

they normally remain positioned proximal to the bladder neck, some may prolapse through the urethra during micturition, almost always in infancy, and result in urinary retention and a relative urologic emergency (Gingell et al, 1971). Depending on the length of time that the ureterocele has been prolapsed, it may vary in color from pink to dusky purple (Fig. 149-9). If a prolapsed ureterocele is in the differential diagnosis, bladder-renal ultrasonography should be performed to look for upper pole hydronephrosis in a duplicated collecting system (Fig. 149-10).

Treatment of a prolapsed ureterocele consists of either needle decompression or incision and reduction and then placement of a urethral catheter. Although this occasionally can be achieved in the emergency department setting, abdominal straining by the infant may make this procedure difficult, and treatment under general anesthesia often is preferable. Injection of radiographic contrast material into the ureterocele can be helpful in identifying the relevant anatomy.

Ectopic Ureteral Insertion

In females an ectopic ureter may enter distal to the urethral sphincter. Ectopic ureters to the vestibule are typically associated with

diurnal incontinence in the presence of normal voiding habits (Fig. 149-11). Most commonly the ureter subtends an upper pole of a duplex system. However, single-system ectopic ureters also may manifest in this fashion and on occasion can be associated with apparent complete absence of the kidney. A thorough search for an ectopic kidney at times may prove fruitful in identifying the cause of the patient's wetting (Borer et al, 1998).

KEY POINTS: DISORDERS OF THE CLITORIS, VESTIBULE, AND URETHRA

- A diminutive clitoris is seen in patients with CAIS.
- Most children with labial adhesions do not require treatment unless they are symptomatic.
- Workup for a child with an introital (interlabial) mass that appears to be associated with the urethra always should include renal-pelvic ultrasonography.
- Urethral prolapse occurs most often in prepubertal black girls and in postmenopausal white women.

Disorders of the Vagina***Imperforate Hymen and Hymenal Skin Tags***

Hymenal skin tags are virtually a normal finding and are rarely symptomatic (Fig. 149-12). When symptomatic (i.e., bleeding), they should be excised to ensure that they do not represent a malignancy and to provide symptomatic relief. Congenital abnormalities of the hymen are not uncommon and range from an imperforate hymen to one with numerous small microperforations.

Imperforate hymen is probably the most common congenital obstructive anomaly of the female reproductive tract. The diagnosis is most frequently made at birth by noting the presence of a bulge along the posterior aspect of the introitus, which represents retained fluid within the vagina, or by palpation of a suprapubic mass from a distended vagina (Fig. 149-13). The buildup of retained vaginal secretions in the neonatal period, which imparts a whitish appearance to the bulging hymenal membrane, is caused by maternal estradiol stimulation. If the diagnosis is made after the neonatal period, the mucus often will have been reabsorbed and a bulge in the hymenal membrane may no longer be evident. On occasion, the diagnosis is not made until the adolescent period, when the patient experiences amenorrhea and possibly cyclic abdominal pain. In these circumstances, a bluish bulging hymen may be observed on genital inspection and a mass will be appreciated on rectoabdominal palpation. In newborns, repair by incision of the hymenal tissue at the bedside is performed in the transverse direc-

tion to avoid inadvertent extension of the incision anteriorly or posteriorly (which might injure the urethra or rectal structures). Simple aspiration of the vagina without a definite drainage procedure should be discouraged because incompletely evacuated material may be prone to ascending bacterial growth. In pubertal girls, general anesthesia with excision of excess hymenal tissue may be indicated (Fig. 149-14).

Acquired abnormalities of the hymenal ring usually result from sexual abuse. The associated finding of a hematoma, abrasion, or laceration in combination with hymenal transection should raise the possibility of this diagnosis. Proper examination under anesthesia and forensic swabbing of affected areas should be undertaken with the use of a standardized protocol.

Abnormalities of Vertical Fusion

Transverse Vaginal Septum. Transverse vaginal septa are believed to arise from a failure in fusion or canalization (or

Figure 149-15. Transverse vaginal septum. A, High (upper vagina). B, Middle. C, Low.

both) of the urogenital sinus and müllerian ducts. The estimated incidence of transverse vaginal septum is 1 in 70,000 females (Banerjee and Laufer, 1998). Many of the patients have amenorrhea and a distended upper vagina. A complete transverse vaginal septum may be located at various levels in the vagina, but there is a higher frequency in the middle and upper third of the vagina. In one large series the distribution was 46% in the upper vagina, 40% in the middle vagina, and 14% in the lower vagina (Fig. 149-15) (Lodi, 1951). The septa are usually less than 1 cm thick and frequently have a small central or eccentric perforation (Suidan and Azoury, 1979). Even in cases in which a perforation is present, significant obstruction and ascending infection can occur. Transperineal, transrectal, and abdominal ultrasonography and MRI may be beneficial in establishing the diagnosis and determining the location and thickness of a transverse vaginal septum (Ammann et al, 1983; Doyle, 1992; Meyer et al, 1995; Caloia et al, 1998; Fedele et al, 1999; Lang et al, 1999). MRI can help determine whether a cervix is present so that a high septum can be differentiated from congenital absence of the cervix. Failure to differentiate between these diagnoses can result in significant patient morbidity (Casey and Laufer, 1997).

Several surgical treatment modalities have been developed to treat congenital transverse vaginal septa. If the patient's pain from hematocolpos is manageable, surgery may be delayed with suppression of endometrial activity by a gonadotropin-releasing hormone (GnRH) agonist or continuous oral contraceptives (Beyth et al, 2004). This may allow time for dilation of the lower vaginal segment, potentially improving the ease of surgical repair. Techniques include simple incision (Brenne et al, 1965; Buttram, 1983), surgical excision of the septum followed by approximation of the corresponding portions of the transversely cut edges of the upper and lower mucosal membranes of the septum (Rock et al, 1982) and the use of Z-plasties involving vaginal mucosa (Wierrani et al, 2003). Recently we described a method that improves the safety of entering the obstructed vaginal segment and subsequently excising the septum (Keenan and Kaefer, 2010). Under ultrasound guidance a 14-gauge angiocatheter is placed through the thick transverse septum. After aspiration reveals thick blood, a 0.35-mm Sensor wire (Boston Scientific, Marlborough, MA) is placed through the angiocatheter and the NephroMax (Boston Scientific) balloon dilating

Figure 149-16. Balloon-assisted division of transverse vaginal septum. A, Hematocolpos on magnetic resonance imaging resulting from transverse vaginal septum. B, Angiocatheter placed into transverse vaginal septum (placed under ultrasound guidance). C, NephroMax balloon dilating the septum.

system is placed over the wire. The balloon is insufflated and subsequently removed, providing a generous aperture through which the remainder of the septum can be excised (Fig. 149-16).

Vaginal stenosis at the site of resection is the most common complication (Joki-Erkila and Heinonen, 2003). The primary advantage of a Z-plasty is that as the suture line contracts the incision is more likely to take on a longitudinal rather than a transverse orientation. Placement of a vaginal mold subsequent to surgery has been reported to further reduce the risk for postoperative stenosis (Bijsterveldt and Willemsen, 2009). Characteristics of molds for transverse septa are different from those used after a McIndoe vaginoplasty (see later). Whereas a solid mold may be used after a vaginoplasty skin graft (because there is no uterus), the mold used after resection of a transverse septum is ideally hollow, to allow egress of menstrual flow.

Vaginal Atresia (Distal Vagina). Vaginal atresia occurs when the urogenital sinus fails to contribute to formation of the lower (distal) portion of the vagina. This condition differs from vaginal

agenesis and testicular feminization in that the müllerian structures are not affected. As a result, the uterus, cervix, and upper portion of the vagina are normal. A very shallow dimple caudal to the urethral opening may be appreciated on physical examination. Palpation of a distended vagina on rectal examination may help distinguish this condition from testicular feminization or vaginal agenesis. Radiographic evaluation in the form of ultrasonography or MRI, or both, is mandatory to adequately define the müllerian anatomy before intervention.

Surgical correction consists of a transverse incision at the level of the hymenal ring. Dissection is carried out through the fibrous area of the absent lower vagina until the upper vagina is reached. As in treatment of a transverse vaginal septum, distention of the vagina with retained menstrual blood products can prove extremely beneficial in that it acts as a tissue expander. After the obstruction is drained and the vaginal mucosa is identified, a pull-through procedure can be performed to bring the distended vagina down to the introitus. The distance to bridge between the vagina and the perineal surface almost always can be successfully managed with perineal skin flaps or simple mobilization of the vagina (or both). [Ramenofsky and Raffensperger \(1971\)](#) described a combined abdominoperineal approach that can be of help in exposing and anastomosing the distal vagina to the perineal skin.

Vaginal Agenesis (Müllerian Aplasia). Vaginal agenesis, which occurs at an incidence of approximately 1 in 5000 live female births, is congenital absence of the proximal portion of the vagina in an otherwise phenotypically (i.e., normal secondary sexual characteristics), chromosomally (i.e., 46,XX), and hormonally (i.e., normal levels of luteinizing hormone and follicle-stimulating hormone) intact female ([Bryan et al, 1949](#); [Griffin et al, 1976](#)). Although Renaldus Columbus is credited by some authors as the first to describe a case of vaginal agenesis, [Mayer \(1829\)](#) was one of the first to report vaginal agenesis in stillborn children ([Lesavoy, 1985](#)).

In 1838, [Rokitansky \(1838\)](#) reported 19 adult autopsy cases of uterovaginal agenesis, including 3 with associated unilateral renal agenesis. In 1910, [Küster \(1910\)](#) recognized urologic associations, such as renal ectopy and agenesis, along with skeletal deformities. [Hauser and Schreiner \(1961\)](#) brought further attention to the frequent association of renal and skeletal anomalies in these patients and stressed the differences between patients with these findings and those with testicular feminization.

The Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome, as the entity of müllerian aplasia has come to be known, results from failure of the sinovaginal bulbs to develop and form the vaginal plate ([Fig. 149-17](#)). This may be caused by improper induction of the sinovaginal bulbs from the neighboring uterovaginal primordium. Chronologically, the uterovaginal canal develops at a point in embryogenesis during which other critical mesodermally derived organ systems are also forming, which in part explains the many associated findings. Müllerian aplasia also has been associated with maternal deficiency of galactose-1-phosphate uridylyltransferase ([Cramer et al, 1996](#)). In contrast to vaginal atresia, the hymenal fringe is usually present, along with a small vaginal pouch, because they are both derived embryologically from the urogenital sinus. Most patients with MRKH syndrome are initially evaluated by the physician after the expected age of menarche because of primary amenorrhea. This syndrome is in fact second only to gonadal dysgenesis as a cause of primary amenorrhea. A minority of patients have cyclic abdominal pain caused by retention of menstrual blood in the uterus. Physical examination reveals absence of the vagina. Inguinal hernia is less common in this disorder than in the testicular feminization syndrome ([Schmid-Tannwald and Hauser, 1973](#)). The karyotype is that of a normal 46,XX woman. Radiographic evaluation is indicated to more fully delineate remnant müllerian structures and search for associated anomalies involving the renal and skeletal systems.

Figure 149-17. Forms of vaginal obstruction. A, imperforate hymen; B, transverse vaginal septum; C, vaginal agenesis. (From Yerkes EB, Rink RC. What urologists should know about pediatric gynecologic abnormalities. *Contemp Urol* 2002;14:12.)

Associated Findings. MRKH syndrome is associated with variable absence or hypoplasia of the cervix, uterus, and fallopian tubes. In approximately 10% of patients, a normal but obstructed uterus or a rudimentary uterus with functional endometrium is present (Murray and Gambrell, 1979; Singh and Devi, 1983; Bates and Wiser, 1985). In one of the largest single series to date, Salvatore and Lodovici (1978) reported that of 91 patients with vaginal agenesis, almost 25% lacked a uterus, 55% had a solid rudimentary uterus, and the remaining 30% had other abnormalities of this organ. In addition, they demonstrated that although the fallopian tubes were normal in 32% of cases, they were rudimentary in almost 50% and completely absent in 10%. Although occasionally cystic, the ovaries were almost always present and functional (Salvatore and Lodovici, 1978). It was subsequently recognized, based on the morphology of the retained müllerian structures, that MRKH syndrome could be divided into typical and atypical forms (Schmid-Tannwald and Hauser, 1977).

In the typical form of MRKH syndrome (type A), the patient has symmetrical uterine remnants and normal fallopian tubes. The atypical form (type B) is characterized by asymmetrical uterine buds or abnormally developed fallopian tubes. This distinction is important because the overwhelming majority of associated findings in other organ systems have been reported to be present with the atypical form, whereas in the typical form these findings are usually absent (Strubbe et al, 1992, 1993).

The association between vaginal agenesis and developmental abnormalities of the kidney was first recognized by Rokitansky (1838). Approximately a third of patients are found to have abnormal renal findings on intravenous pyelography or ultrasound examination (Strubbe et al, 1993). Renal anomalies are present almost exclusively in patients with the atypical subtype of vaginal agenesis (type B). In the series by Strubbe and colleagues (1993), 34 of 51 patients with type B anatomy had renal anomalies, but none of the 40 patients with type A (symmetrical) anatomy demonstrated such a deformity. A meta-analysis published by Griffin and associates (1976) demonstrated that the renal anomaly consists of either unilateral renal agenesis or ectopia of one or both kidneys in 74% of those affected. The close proximity of the mesonephric and paramesonephric structures during the early phase of fetal development is thought to be the reason for this frequent association of renal anomalies. Not surprisingly, the converse is also true: the incidence of associated genital abnormalities in female patients with renal anomalies ranges between 25% and 89% (Thompson and Lynn, 1966).

Associated congenital abnormalities of the skeletal system have been described in 10% to 20% of cases (Turunen, 1967; Willemssen, 1982; Strubbe et al, 1987). Congenital fusion (failure of segmentation) of the cervical vertebrae is known as the Klippel-Feil syndrome and occurs approximately once in 30,000 to 40,000 live births (Gunderson et al, 1967). An association between this abnormality of cervical somite development and vaginal agenesis was first recognized by Duncan (1977). He proposed the term *MURCS association* to describe the combination of müllerian duct aplasia, Renal aplasia, and Cervicothoracic Somite dysplasia, which many believe is caused by a generalized disordered development of mesodermal differentiation during the fourth week of fetal life (Duncan et al, 1979). Strubbe and colleagues (1992) demonstrated that the Klippel-Feil abnormality was found only in patients with the atypical form of MRKH syndrome (type B). Additional, albeit less common, skeletal abnormalities include scoliosis and abnormalities of the hands and face (Willemssen, 1982; Fisher et al, 2000). Unlike müllerian anomalies that are associated with abnormal cloacal septation, vaginal agenesis is not associated with an increased incidence of lumbosacral spinal disorders or occult spinal dysraphism (Gunderson et al, 1967).

Vaginal Replacement Surgery

Creation of a Skin Neovagina. Both nonoperative and operative treatment options exist for this anomaly. Regardless of the method used, it can be very helpful to have the patient speak with someone who has previously undergone treatment before treatment is initiated (Ingram, 1981). The nonoperative approach, initially popu-

KEY POINTS: DISORDERS OF THE VAGINA

- Anomalies of the female reproductive system can be grouped into three main categories, those resulting from (1) hypoplasia or agenesis, (2) vertical fusion, and (3) lateral fusion.
- Transverse vaginal septa are believed to arise from a failure in fusion or canalization (or both) of the urogenital sinus and müllerian ducts.
- Vaginal atresia occurs when the urogenital sinus fails to contribute to formation of the lower (distal) portion of the vagina.
- Vaginal agenesis is congenital absence of the proximal portion of the vagina in an otherwise phenotypically, chromosomally, and hormonally intact female.
- MRKH syndrome, as the entity of müllerian aplasia has come to be known, results from failure of the sinovaginal bulbs to develop from the vaginal plate.

larized by Frank (1938), involves gentle pressure of graduated hard dilators against the perineal surface to create a progressive invagination of the vaginal dimple. Ingram (1981) modified this technique by using a bicycle seat mounted on a stool. The nonoperative approach has greatest success when a vaginal dimple or pouch is already present (Williams et al, 1984, 1985). Gargollo and colleagues (2009) recently reported their experience with 69 females (mean 17.5 years) with vaginal agenesis treated with progressive perineal dilation. Success, defined as the ability to achieve sexual intercourse, vaginal acceptance of the largest dilator without discomfort, or a vaginal length of 7 cm, was achieved in 88% of patients. The authors concluded that progressive perineal dilation should be offered as first-line therapy in adolescents with congenitally absent vagina.

Modifications of the Frank technique of perineal pressure have been developed that incorporate the surgical placement of tension sutures to aid in directing pressure from a Plexiglas dilator against the vaginal dimple (Vecchietti, 1979). The mold, often referred to as an "olive," has sutures attached to it that are guided in a cranial direction through the vesicorectal space into the perineal cavity and brought out through the abdominal wall (Vecchietti technique). Tension is progressively increased via the abdominal wall sutures until sufficient vaginal length has been achieved. To avoid a formal laparotomy, laparoscopic techniques have been described to assist in dissection of the tissue plane for the Vecchietti technique (Borruto, 1992; Gauwerky et al, 1992; Fedele et al, 1996, 1999; Brucker et al, 2008). In the more recent series by Fedele and colleagues (2006), all patients were found to have healthy vaginal mucosa, with the average vaginal length being almost 8 cm at 3 months. This had limited use by urologists.

If the Frank method has been unsuccessful or is not accepted as a reasonable option by the patient or parents, creation of a functional vagina can be achieved by one of several techniques (Abbé, 1988; McIndoe and Banister, 1938; Hendren and Atala, 1994). The first landmark advance in vaginal reconstruction is attributed to Abbé in 1898. Abbé described dissecting a canal between the rectum and urethra and lining this area with split-thickness skin grafts. This method was later popularized by McIndoe, and the procedure that bears his name has gained wide acceptance in the United States (McIndoe and Banister, 1938). Preoperative preparation consists of full mechanical and antibiotic bowel preparation. A split-thickness skin graft is taken from the buttocks (0.018 to 0.022 inch) and tubularized over a stent (Fig. 149-18). A transverse incision is made at the level of the perineal dimple, and the potential space between the urethra and the rectum is carefully dissected up to the level of the peritoneal reflection. The graft and mold are then inserted into the potential space, and the labia minora are sutured around the stent to prevent extrusion during the initial healing phase (McIndoe, 1950). Many types of vaginal stents have been used for this purpose, including packed gauze, wood covered with a condom, silicone foam, acrylic, various metals, and an

Figure 149-18. McIndoe skin vagina sewn over a vaginal stent.

inflatable vaginal stent (Concannon et al, 1993; Chen, 1994; Barutcu and Akguner, 1998). The Foley catheter is replaced by a suprapubic catheter, and postoperatively the patient is kept at strict bed rest for 1 full week. A high incidence of postoperative vaginal stenosis necessitates postoperative vaginal dilation (Ingram, 1981). Excellent patient satisfaction has been reported in most large series (Martinez-Mora et al, 1992; Strickland et al, 1993; Alessandrescu et al, 1996).

Other options for creation of a neovagina with local tissues include the use of full-thickness skin grafts from the buttocks or full-thickness skin flaps based on the labia majora. Those who champion the use of full-thickness skin grafts report a lower incidence of graft contracture than when split-thickness graft techniques are used (Sadove and Horton, 1988). The Williams (1964) vaginoplasty involves the creation of a vaginal pouch from the labia majora. The combination of this procedure and Frank-type dilation along the vaginal axis can provide a satisfactory result.

Many other surgical procedures have been developed for creation of a functional neovagina with various muscle flaps (e.g., pudendal thigh, rectus abdominis, buttock) (McCraw et al, 1976; Lilford et al, 1989; Dumanian and Donahoe, 1992; Wang and Hadley, 1993; Joseph, 1997). The pelvic peritoneum and human amnion are two other donor sites that have been used to create a neovagina (Davydov, 1977; Ashworth et al, 1986; Morton and Dewhurst, 1986; Tamaya and Imai, 1991; Marquis et al, 2008).

Creation of an Intestinal Neovagina. Baldwin first described the use of bowel for creation of the vagina in 1907. The procedure involved anastomosis of a U-shaped segment of sigmoid colon to the perineum with subsequent division of the intervening septum (Hensle and Dean, 1992). Additional experience with this technique was reported by Fall in 1940, but it did not gain widespread acceptance until the 1970s because of high patient morbidity and mortality (Fall, 1940; Pratt, 1972). Subsequent improvements in technique and postoperative care resulted in renewed enthusiasm for these techniques (Turner-Warwick and Kirby, 1990; Hendren and Atala, 1994; Hensle and Reiley, 1998; Tillem et al, 1998). Sigmoid, cecum, and small intestine have been used successfully for the creation of a functional neovagina.

The day before surgery, the patient undergoes full mechanical and antibiotic cleansing of the alimentary tract. The procedure is performed with the patient supine, the legs spread, and the knees bent (frog-leg position). In an older child, Allen stirrups can be used. For a sigmoid vaginoplasty, the intra-abdominal portion of the procedure begins by first identifying an appropriate length of distal sigmoid with a blood supply that will comfortably reach the perineum (Fig. 149-19). The distal end of the proposed segment is then divided and anastomosed to the perineum (Fig. 149-20). An intervening segment of sigmoid (~3 cm) is then excised to create a space between the oversewn proximal edge of the bowel vagina and the end of the sigmoid, which is anastomosed to the rectum. This maneuver prevents an overlap of suture lines and thereby has the potential advantage of limiting the incidence of fistula formation. The bowel vagina is thereafter fixed to the posterior peritoneum to prevent prolapse. Gosalbez (personal communication, 2009) described a modified Monti technique of bowel detubularization

Figure 149-19. Sigmoid segment harvested for bowel vagina. Clamp on peritoneum.

for vaginal replacement that can aid in allowing the segment to reach the perineum. By opening the colonic segment close to its mesentery along one side of the bowel and then retubularizing in a Heineke-Mikulicz fashion, as described by Monti, the reconfigured segment allows for the mesentery to be located at the most cranial end of tube and allows the caudal end to extend more distally.

Although we have had the most success with the sigmoid, a small-bowel segment may be chosen with a vascular pedicle that is of adequate length to reach the perineum. After isolating an appropriate length of ileum and reestablishing bowel continuity, the segment is detubularized and reconfigured in a conical arrangement to provide increased internal diameter (Hendren and Atala, 1994). The segment is then brought down to the perineum and sewn in place, as for a sigmoid neovagina. To avoid a formal laparotomy, laparoscopically assisted techniques have been described for harvest and delivery of the bowel segment to the perineal location (Ota et al, 2000).

If there is a perineal dimple (i.e., the segment of vagina contributed by the urogenital sinus is present), the bowel segment should be anastomosed directly to it. When a direct perineal anastomosis is required, it is of critical importance to create a large enough space between the rectum and bladder to avoid compromise of the intestinal blood supply. Creation of such a space can be facilitated by the use of progressively larger Hegar dilators. Gentle passage of the intestinal segment into position is facilitated by placing the segment in a large lubricated Penrose drain before transfer to the perineum.

The functional results of bowel vaginoplasty have been excellent. Of the 65 patients reported by Hendren and Atala (1994), 16 experienced mild eversion of the bowel segment, which in every case was amenable to simple trimming. Eight patients experienced mild stenosis that was later corrected by appropriate Z-plasties to increase the circumference of the mucocutaneous junction. Patient satisfaction is high, and the majority of patients who are old enough to engage in sexual relations are able to achieve adequate coitus (Hensle and Reiley, 1998).

Stenosis has been reported more frequently after the use of ileum (Hensle and Dean, 1992). This higher stenosis rate may be due not only to the more narrow ileal lumen but also to the limited mobility of the small bowel mesentery. As a result, the authors and others believe that large intestine is the bowel segment of choice. Two specific indications for use of an ileal segment for bowel vaginoplasty are previous irradiation of the deep pelvis and the absence of large intestine (i.e., cloacal exstrophy). When ileum is used, various methods of reconfiguration can be used to increase the diameter (Hendren and Atala, 1994). Advantages of a bowel vagina over the McIndoe procedure include the lubricating properties of mucus (which may help facilitate

Figure 149-20. A, Vaginal agenesis. B, Harvest of colonic segment and creation of vaginal space. C, Colonic segment sewn in place.

intercourse) and the decreased incidence of postoperative contracture (and hence the reduced need for postoperative dilation). Disadvantages include the frequent need to wear pads because of the chronic vaginal discharge. Daily douching may be necessary to evacuate the mucus. Finally, the potential transmission of blood-borne pathogens such as hepatitis and human immunodeficiency virus may be increased (in comparison to a squamous epithelium-lined vagina) because of the poor barrier effect of the gastrointestinal tract.

All patients undergoing creation of a functional vagina with perineal skin require annual examination because there have been reports of condylomata acuminata and squamous cell carcinoma involving grafts (Duckler, 1972; Rotmensch et al, 1983; Buscema et al, 1987). Annual examination of the bowel vagina is also indicated because adenocarcinoma has been identified after this procedure (Andryjowicz et al, 1985).

The optimal timing of surgery remains a source of debate. The majority of surgeons who favor the McIndoe procedure for

construction of a neovagina think it is better to wait until adulthood to perform the procedure because a degree of maturity is required to consistently perform daily dilations. Many surgeons who favor the use of bowel for neovaginal reconstruction do not think vaginoplasty should be deferred until the patient reaches adulthood. [Hendren and Atala \(1994\)](#) think that delaying creation of a neovagina until adulthood may be psychologically traumatic to a young girl. The authors have based timing on the underlying diagnosis and need for a neovagina.

Special Considerations: Cervical Atresia. Cervical agenesis is an uncommon disorder that is associated with symptoms common to other obstructive entities of the female reproductive tract (i.e., primary amenorrhea, cyclic or chronic abdominal pain). Failure to establish the correct diagnosis and thereby choose the appropriate method of surgical intervention can be fraught with disaster and possible patient mortality. MRI is the most useful radiographic modality in establishing this diagnosis ([Fig. 149-21](#)). In many circumstances the patient is best served by hysterectomy with subsequent vaginal replacement by one of the previously described techniques ([Rock et al, 1982](#); [Cukier et al, 1986](#)). Successful direct anastomosis of the neovagina to the uterine remnant has been reported. [Deffarges and coworkers \(2001\)](#), in describing their experience with uterovaginal anastomosis, reported a 40% pregnancy rate in patients attempting to conceive. Cerclage was performed in only one case. All deliveries were by cesarean section. Although this procedure appears to be successful in the majority of cases, absence of the normal endocervical barrier can leave the patient predisposed to the development of life-threatening ascending infection ([Maciulla et al, 1978](#); [Niver et al, 1980](#); [Casey and Laufer, 1997](#)).

In cases in which it has not been possible to successfully achieve continuity between the uterus and vagina, in vitro fertilization plus transmyometrial embryo transfer has been performed, with subsequent delivery of a healthy fetus by cesarean section ([Anttila et al, 1999](#); [Lai et al, 2001](#)). If this option is considered, hormonal blockade of the endometrium until the time at which the patient desires to initiate a pregnancy is indicated to minimize discomfort and reduce the incidence of endometriosis from retrograde menstrual flow in the fallopian tubes.

Figure 149-21. Magnetic resonance imaging scan of the pelvis in a 12-year-old girl with Klippel-Feil syndrome and associated proximal vaginal and cervical atresia. The *solid arrow* points to the most cranial portion of the perineal vaginal pit. The *dashed arrow* points to the most inferior aspect of the uterus, where no cervical impression can be appreciated.

KEY POINTS: VAGINAL REPLACEMENT SURGERY

- The McIndoe procedure (skin neovagina) is associated with a higher incidence of postoperative vaginal stenosis than a bowel neovagina.
- Vaginal stenosis after creation of an intestinal neovagina is more common with ileum than with large bowel.
- Vaginal reconstruction extending from the perineum to the uterus should be avoided in patients with cervical agenesis (because of the potential life-threatening complication of ascending bacterial infection).

Abnormalities of Lateral Fusion

Most abnormalities of lateral fusion have no functional significance. With the exception of those with uterus didelphys and unilateral vaginal obstruction, most patients are asymptomatic. Although an exhaustive description of the defects of lateral fusion is beyond the scope of this chapter, some general comments can be made ([Fig. 149-22](#)).

True duplication of the uterus is a rare event ([Fig. 149-23](#)). This anomaly results from duplication of the müllerian ducts and subsequent doubling of the reproductive structures on one or both sides. The much more frequently encountered anomaly of uterine didelphys consists of two separate uterine cavities and cervices as a result of failed resorption of the common medial wall of the paired müllerian duct structures during development. Although up to 75% of patients also have a septate vagina, most have adequate reproductive outcomes and do not require surgical intervention. If later in life the patient experiences difficulty with intercourse, vaginal delivery, or the need to use two tampons, surgical excision of the vaginal septum should be undertaken. If only the most cranial portion of the septum remains, a bicornuate uterus will result. The vagina is typically normal, and surgical incision of the uterine septum is rarely indicated except in cases of recurrent pregnancy loss ([DeCherney et al, 1986](#)).

Duplication of the Uterus and Cervix with a Unilaterally Imperforate Vagina. Although the majority of obstructive lesions are caused by abnormalities in vertical fusion, occasionally an obstructive process can be encountered in the context of

Figure 149-22. Fusion anomalies of the müllerian system. A, Bicornuate uterus (partial). B, Bicornuate uterus. C, Uterine duplication. D, Complete uterine and vaginal duplication. E, Duplication of the uterus and cervix with a unilateral imperforate vagina. (From Yerkes EB, Rink RC. What urologists should know about pediatric gynecologic abnormalities. *Contemp Urol* 2002;14:12.)

Figure 149-23. Genitogram of complete müllerian duplication (separated vagina and separate uteri).

Figure 149-24. Duplication of uterus and vagina with unilateral imperforate vagina. View through vagina with angiocatheter inserted into obstructed side.

an abnormality in lateral fusion (Fig. 149-24). More than 50 cases of uterus didelphys with a unilateral imperforate vagina have been reported in the world's literature (Allan and Cowan, 1963; Burbige and Hensle, 1984). As with other obstructive disorders, the patient may have cyclic or chronic abdominal pain. However, unlike other obstructive processes, duplication anomalies with unilateral obstruction do not result in primary amenorrhea. On physical examination, a unilateral abdominopelvic mass that termi-

nates in a bluish bulge in the lateral vaginal wall is often appreciated (Eisenberg et al, 1982). Abdominal ultrasonography and MRI are both excellent at defining the anatomy in a suspected case of unilateral noncommunicating uterine horn. Renal anomalies are frequently encountered on the side ipsilateral to the obstructed system, with renal agenesis being the most common (Eisenberg et al, 1982; Tridenti and Bruni, 1995). A prompt and accurate diagnosis is necessary to prevent injury to the genital organs as a result of chronic cryptomenorrhea and endometriosis. Treatment consists of wide incision of the vertical vaginal septum to release the entrapped menstrual blood.

Rhabdomyosarcoma

Vaginal rhabdomyosarcoma most often manifests as a grapelike cluster of tissue emanating from the posterior aspect of the vestibule (Fig. 149-25). The mean age of patients with primary vaginal tumors is younger than 2 years (Hays et al, 1988). Of all the female genital tract primary tumors, vaginal primary tumors appear to have the best prognosis. This excellent prognosis is thought to be a result of predominance of the embryonal cell type and relatively early detection because of symptoms of bleeding (Hays et al, 1988). Once a tissue diagnosis has been made by biopsy, proper staging with abdominal and pelvic computed tomography, chest radiography, and bone marrow biopsy is critical to optimal stratification of these patients into treatment protocols (Hays et al, 1985). Advances in chemotherapy have led to a reduction in the role of surgery for this disease with each subsequent Intergroup Rhabdomyosarcoma Study (IRS) trial: IRS-I, 100%; IRS-II, 70%; IRS-III, 30%; and IRS-IV, 13% (Andrassy et al, 1999). After chemotherapy, local resection may be required, but unlike other malignancies of the vagina, wide excision of the involved organ has no role except for persistent or recurrent disease (Hensley, 2000).

ACQUIRED DISORDERS OF THE FEMALE EXTERNAL GENITALIA

Labial Adhesions

Labial adhesions, also referred to as labial agglutination, and synechia vulvae are the most common interlabial abnormality identified in children, ranging in incidence from 0.6% to 1.8%

Figure 149-26. Labial adhesions.

(Leung et al, 1993; Norbeck et al, 1993). This condition occurs predominantly in the first 2 years of life, with a peak incidence between 13 and 23 months (Fig. 149-26). Fusion of the labia minora originates at the posterior fourchette and progresses for a variable distance toward the clitoris. It is important to differentiate this condition from the more serious entity of fusion of the labia majora, as is seen in certain disorders of sexual development. It has been hypothesized that hypoerogenism may play a role in adhesion of the labia minora. Labial adhesions have not been reported in newborn children, presumably because of the protective effect of maternal estrogen (Leung et al, 1993). However, the etiologic role of the hypoerogenic state has been brought into question by a number of authors (Caglar, 2007; Pulvino et al, 2008). Caglar (2007) measured circulating estradiol levels in 59 girls with labial adhesions and 60 control patients. He demonstrated no difference in the circulating level of estrogen in these two patient groups. It has been shown that estradiol may enhance wound re-epithelialization by promoting heparin-binding epidermal growth factor production in keratinocytes (Kanda and Watanabe, 2005). If there is a beneficial effect of topical estrogen it may be to promote healing after the adhesions have been separated. Nonhormonal factors may play an etiologic role in the formation of labial adhesions (Papagianni and Stanhope, 2003). Local irritation and tissue trauma appear to be important inciting events in many cases. Adhesions can rarely be associated with sexual abuse; in such cases, additional physical findings are often noted, including hematoma and lacerations (McCann et al, 1988). Although labial adhesions are usually asymptomatic, urine pooling within the vagina may lead to postvoid dribbling and perineal irritation and may make it difficult to obtain an accurate urinalysis sample or perform radiographic procedures.

Most children with labial adhesions do not require treatment unless they are symptomatic. With the rate of spontaneous resolution reported to be as high as 80% within 1 year, asymptomatic labial adhesions can comfortably be observed (Pokorny, 1992). When necessary, treatment ranges from the topical application of

various steroids to surgical division. The topical application of conjugated estrogens has been reported to be successful in separating adhesions in up to 90% of patients (Khanam et al, 1977; Leung et al, 2005). Concern over the possible side effects of breast budding and hyperpigmentation from prolonged use of conjugated estrogen led Myers and associates (2006) to treat a cohort of 19 prepubertal patients with topical betamethasone (0.05%). The authors reported success in 13 (68%) patients after administering one to three courses of twice-daily therapy for 4 to 6 weeks. It is important to have the family place the cream directly on the labia minora. In addition, it is helpful to have the family perform the pull-down procedure a few times a day to put light stress on the midline adhesions and hence facilitate their separation. If topical therapy is not successful, manual separation in the outpatient setting may be indicated. After the application of EMLA cream to the introitus, gentle pressure is applied to the thin connecting membrane with the use of a lubricated probe. Rarely, in cases in which the adhesions are extremely dense, surgical division is required. Although one group has recently advocated oversewing the separated edges with 7-0 chromic sutures (Nurzia et al, 2003), I have not found this to be necessary if the family is properly educated about keeping the labia separated (see Fig. 149-2) after the procedure. Recurrence rates appear to be similar when comparing children who have undergone manual separation (16.7%) versus surgical separation (15.4%), emphasizing the importance of having families continue to separate the labia after separation has been achieved (Muram, 1999).

Female Circumcision (Infibulation)

Acquired vaginal obstruction may be secondary to a number of ritual female genital mutilation procedures that are widespread in many countries in Africa (stretching in a band from the Horn of Africa through Central Africa to parts of Nigeria), the Middle East, and Muslim populations of Indonesia and Malaysia (Toubia, 1994; Dorkenoo, 1996). Although similar procedures were prescribed to U.S. and British women during the 19th century for the treatment of ailments ranging from epilepsy to lesbianism, all forms of genital mutilation are now illegal in these Western countries. Often referred to as “female circumcision,” the procedure continues to affect an estimated 80 to 110 million women worldwide (Toubia, 1994).

The age at which this procedure is performed ranges from birth to just before marriage. However, it is typically performed on preadolescent children between the ages of 4 and 10 years, most commonly at age 7 (American Medical Association, 1995). The procedure is usually performed without anesthesia in the context of a ceremony designating the rite of passage into adult society (American Medical Association, 1995). The extent of the mutilation varies according to ritual, but the practice predates Islam and is therefore not part of a religion (McCaffrey et al, 1995). In many countries the women have a deinfibulation procedure performed just before consummating the marriage.

The type of mutilation ranges from simple excision of the prepuce of the clitoris (termed *sunna*) to complete excision of all elements of the vulvar region (McCaffrey et al, 1995).

Toubia (1994) classified the more extensive female genital mutilation procedures according to the amount of tissue destruction:

Type I: Complete or partial removal of the clitoris.

Type II: Excision of the clitoris and a portion of the labia minora.

Type III: Excision of the entire clitoris and labia minora with incision of the labia majora along its medial aspect to create raw surfaces. The anterior two thirds of the labia majora are approximated to cover the urethra and introitus, with the lower third at the level of the posterior fourchette left for the passage of urine and menstrual fluid.

Type IV: Excision of the entire clitoris and labia minora with nearly complete approximation of the labia majora and only a pinhole opening left near the posterior fourchette for the passage of urine and menstrual fluid (Fig. 149-27).

Figure 149-27. Female infibulation. Note the scarred labia majora with only a pinhole opening for the passage of menstrual fluid and urine. (From Gonzales ET, Bauer SB, editors. *Pediatric urology practice*. Philadelphia: Lippincott Williams & Wilkins; 1999. p. 599.)

Closing of the introitus, typically referred to as infibulation or pharaonic circumcision, is performed by a variety of means, including absorbable and nonabsorbable suture materials, thorns, and twigs. The child's legs are then bound for up to 40 days to ensure secondary healing in the ventral midline (McCaffrey et al, 1995).

The physical, psychological, and reproductive repercussions of these forms of genital mutilation are numerous and include immediate destruction and infection of local tissues (e.g., rectum, urethra). Long-term risks include chronic pain, recurrent urinary tract and vaginal infections, dysmenorrhea, dyspareunia, and apareunia. For individuals with the most narrowing, additional "surgeries" to revise the introital opening may be necessary for both intercourse and vaginal delivery (Aziz, 1980; Toubia, 1994).

Care of a patient who has undergone infibulation must be individualized, not only to provide functionality but also to respect the cultural and ritual desires of the woman. Educating the patient about the normal appearance of the external female genitalia is critical. Visual aids, including photographs or hand-drawn illustrations (or both) of the patient's anatomy and the planned revision, have been used as part of informed consent to avoid misunderstanding.

Condyloma Acuminatum

The incidence of genital warts in children has increased over the past 5 decades (Leclair et al, 2012). Although the majority will be found in the perianal region, involvement of the vestibule can at times occur. The treatment of condyloma acuminatum in pediatric patients is difficult, with a wide range of treatment options that yield variable success. The decision as to which treatment is most ideal will depend on patient age and location and severity of the

lesions. Although a very high suspicion for sexual abuse is warranted, it should be kept in mind that perinatal transmission is also a possible mechanism. De Jesus and associates (2001) reported that perinatal transmission occurred in 7 of their 17 patients.

Reports of spontaneous resolution have been reported (Leclair et al, 2012). Allen and Siegfried reported that spontaneous resolution of pediatric condyloma occurred in more than half of their subjects (Allen and Siegfried, 1998). Medical therapy can be effective. Imiquimod, an immune response modifier that works through the Toll-like receptor 7 pathway, has been used extensively in adults. Leclair and colleagues found this to be highly effective in a young child with rapidly progressing lesions that were not amenable to surgical resection. Although carbon dioxide laser ablation of anogenital lesions is straightforward, lesions directly involving the vestibule may be more challenging. In one series of 17 patients in whom 12 were female, nearly 70% responded favorably to CO₂ ablation therapy (Johnson et al, 1997). Because the cause of condyloma acuminatum is human papillomavirus, authors emphasize the primary prevention of HPV infection through vaccination as a key component in decreasing the incidence of this disease (Thornsberry and English, 2012).

Inguinal Hernias

Inguinal hernias occur far less frequently in girls than in boys, with a ratio between 1:5 and 1:10 reported in major series. Although usually an isolated event, this anatomic finding can be the manifesting symptom for a child with CAIS. Multiple authors have reported a 1% incidence of CAIS in patients presenting with an inguinal hernia (Sarpel et al, 2005; Hurme et al, 2009). It is therefore imperative that all phenotypic females who present with an inguinal hernia be evaluated to determine if they are a genetic male. Various methods of determining whether the patient has CAIS are available to the clinician. A karyotype, although definitive, is costly and therefore not obtained routinely by most practitioners. Recently, one group evaluated whether extraction of Y chromosome DNA from a buccal mucosal sample was feasible. They found that this test proved less expensive and provided quicker results than a standard karyotype (Rahman et al, 2012). A pelvic sonogram to evaluate for the presence (or absence) of a vaginal stripe also can be obtained, but has the similar drawback of added cost.

Simple evaluation by way of vaginoscopy at the time of hernia repair will reveal if a cervix is present. A patient with CAIS also may have a significantly shorter vagina. While the hernia is being repaired, inguinal laparoscopy can be performed to study the contralateral gonad and evaluate for the presence of uterus. The round ligament will be uniformly absent in genetic males.

Normal Sexual Differentiation

Abnormal Sexual Differentiation

Evaluation and Management of the Newborn with Ambiguous Genitalia

Disorders of sexual differentiation are among the most fascinating and complex disease processes encountered by the urologist. This field has undergone a striking evolution over the past few decades. Remarkable advances in molecular biology and genetic research have provided new insight into the precise mechanisms responsible for sexual differentiation and for specific disorders of sexual development. In addition, there has been a major shift in nomenclature to promote precise communication among colleagues and respect for the sensitivity of patients by eliminating terms such as *pseudohermaphroditism*, which have been regarded as pejorative by patients. The term *intersex disorders* has been replaced by *disorders of sex development* (DSDs).

NORMAL SEXUAL DIFFERENTIATION

Under normal circumstances, sexual differentiation is a dynamic and sequential process. According to the Jost paradigm, three steps must occur: establishment of chromosomal sex at fertilization, which determines development of the undifferentiated gonads into testes or ovaries, and subsequent differentiation of the internal ducts and external genitalia as a result of endocrine functions associated with the type of gonad present (Jost et al, 1973). Therefore sexual development occurs as a result of different but complementary processes: genotypic effects, phenotypic events, and gender identity formation. Interference with this highly ordered process at any step can result in a disorder of sexual differentiation.

Normal Genotypic Development

Chromosomal Sex

In 1921, Painter demonstrated cytologically that humans have X and Y chromosomes. Based on chromosomal studies of *Drosophila*, it was assumed that sex was determined by the X chromosomes possessed by the individual (Bridges, 1921). The Y chromosome was thought to impart no genetic information until karyotyping of mammalian chromosomes, developed in the 1950s, demonstrated that the Y chromosome specified development of the testis. Specifically, reports in the late 1950s describing the karyotype 47,XXY as male with Klinefelter syndrome and 45,XO as female with Turner syndrome demonstrated that the presence of a Y chromosome, independent of the number of X chromosomes, resulted in the development of a male embryo, whereas in the absence of a Y chromosome the embryo developed as a female (Ford et al, 1959; Jacobs and Strong, 1959). Therefore the Y chromosome appeared to possess a gene or genes that determined the destiny of the bipotential gonad as a testis or ovary. In the human, the hypo-

thetical Y-chromosomal gene was termed the *testis-determining factor* (TDF).

During the following years the search for the TDF was the focus of intense research. The observation that antibodies raised in inbred female mice transplanted with male skin grafts resulted in graft rejection whereas female-to-male skin grafts were accepted in the same strain of mice led to the proposal that the histocompatibility-Y, or H-Y, antigen was the product of TDF (Eichwald and Silmser, 1955). Assays for quantifying H-Y antigen were developed. With the use of these assays it was discovered that the presence of a testis resulted in serologically detectable levels of H-Y antigen. This was confirmed in normal patients, patients with DSDs, and males of other species. Therefore it was believed that the H-Y gene was the TDF (Wachtel, 1977). This theory was considered valid for more than 10 years.

Problems with the H-Y antigen theory developed, however. A number of women with 45,X gonadal dysgenesis were found to be H-Y antigen positive. In addition, a mouse model for the male sex reversal syndrome (XX male) was studied in which mice have two X chromosomes and testes owing to a fragment of Y chromosome translocated onto one of the X chromosomes (McLaren et al, 1984). These mice were H-Y antigen negative and azoospermic. As a result of these findings, the hypothesis that the H-Y antigen was the product of TDF was excluded. Further study of the Y chromosome suggested that the genetic information responsible for maleness was on the short arm of the chromosome near the centromere. This theory was supported by data from animals with naturally occurring sex chromosome abnormalities. Gain or loss of DNA from the short arm of the Y chromosome on an XX genetic background resulted in either a male or female phenotype, respectively. Further progress was made by studying paradoxical 46,XX males who develop as phenotypic males in the presence of a presumably normal female 46,XX karyotype (Magenis et al, 1982). The simplest explanation for their sex reversal would be the presence of Y-chromosomal material (including TDF), as a result of mosaicism or submicroscopic cellular quantities. The application of molecular techniques to evaluate Y-chromosomal sequences present in XX males, as well as deletions of the Y chromosome in XY females, led to the cloning of TDF (Lukusa et al, 1992). Deletion maps based on the genomes of these individuals were constructed by a number of laboratories, and TDF was mapped to the most distal aspect of the Y-unique region of the short arm of the Y chromosome, adjacent to the pseudoautosomal boundary (Fig. 150-1).

ZFY and SRY

Page and coworkers (1987) constructed a more detailed genomic map and defined a 140-kilobase (kb) interval thought to contain

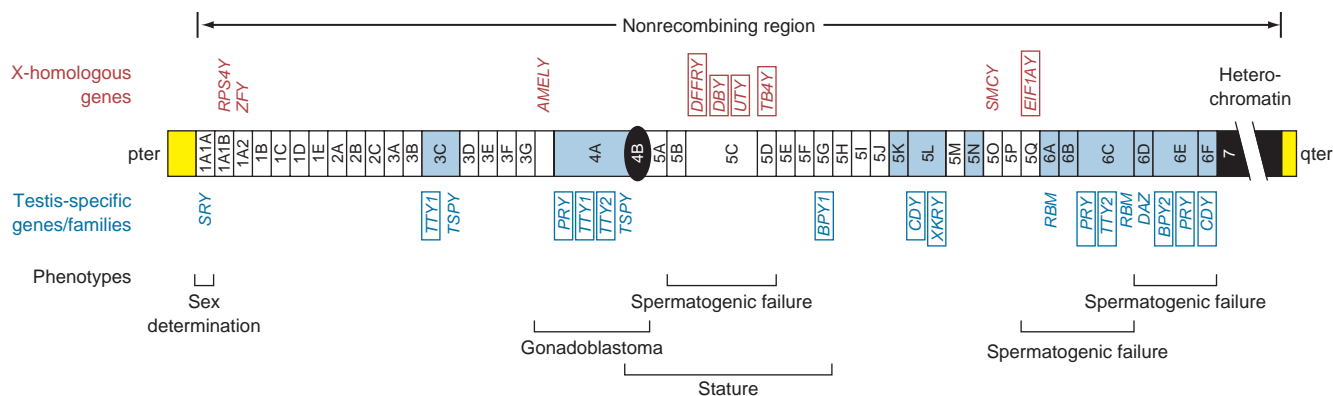

Figure 150-1. Genetic map of the short arm of the human Y chromosome. The pseudoautosomal region, where genetic crossing over may occur between sex chromosomes, is highlighted in yellow. The *SRY* and *ZFY* loci are located near the pseudoautosomal boundary on the short arm of the Y chromosome at the terminal end (pter). The *SRY* gene encodes the molecular switch that promotes gonadal sex determination. (Modified from Lahn BT, Page DC. Functional coherence of the human Y chromosome. *Science* 1997;278:675–80.)

Figure 150-2. Diagrammatic representation of the historical search for the testis-determining factor (TDF). The area shaded in black on the Y chromosome is the region to which this factor has been localized. (From Grumbach MM, Conte FH. Disorders of sex differentiation. In: Wilson JD, Foster DW, editors. *Williams textbook of endocrinology*. Philadelphia: Saunders; 1998. p. 1315.)

the TDF by aligning the Y-specific DNA present in an XX male with a Y chromosome deletion of the same region in an XY female. These investigators identified a gene encoding a protein with multiple "zinc finger" domains, characteristic of a class of proteins that bind DNA in a sequence-specific manner and regulate transcription. In addition, these sequences demonstrated evolutionary conservation. Based on its position and structural similarity to other transcription factors, *ZFY* (zinc finger gene on Y chromosome) was proposed as a candidate for the TDF.

However, in subsequent years, data were accumulated that excluded *ZFY* as the TDF. This included the discovery that in marsupials *ZFY* was located not on the sex chromosomes but on autosomes (Sinclair et al, 1988). *ZFY* was excluded with certainty as a candidate for TDF when four individuals with testicular development were found to have inherited a fragment of the Y chromosome that did not include *ZFY* (Palmer et al, 1989).

The renewed search for TDF led to the discovery of Y-specific sequences in XX males lacking *ZFY* and the imposition of new limits on the location of TDF to a 35-kb region adjacent to the pseudoautosomal boundary (Fig. 150-2). Using probes from this region, Sinclair and colleagues (1990) discovered a single-copy male-specific sequence that was evolutionarily conserved. This

gene was termed *SRY* (sex-determining region Y gene) in humans and *Sry* in mice. Analysis of the *SRY* protein sequence demonstrated a highly conserved, 78-amino acid region with homology to a DNA-binding motif of the high-mobility group (HMG) family of proteins (Fig. 150-3). When DNA encoding the HMG box was used to probe a genomic library, a subfamily of closely related genes was identified. Members of this family, defined as those encoding a region with 60% or greater amino acid similarity to the *SRY* HMG box motif, are called SOX (SRY box-related) genes (Goodfellow and Lovell-Badge, 1993).

Considerable evidence has accumulated that *SRY* is the TDF. In the mouse, expression of *Sry* correlates with testicular determination in the gonadal ridge (Koopman et al, 1990). *SRY* is an evolutionarily conserved gene on the Y chromosome of mammals. Chromosomal fragments related to *SRY* (i.e., the SOX genes) are very much conserved evolutionarily, being demonstrated in various vertebrates and marsupials. *SRY* is localized to the smallest region of the Y chromosome capable of inducing testicular differentiation in humans and in mice (Gubbay et al, 1992). In fact, Koopman and coworkers (1991) introduced into XX mouse embryos a 14-kb mouse genomic DNA fragment containing *Sry* and no other Y-linked gene sequences and demonstrated that it was capable of giving rise

to normal testicular development in the transgenic mice. The *SRY* protein functions as a transcription factor that, by binding and producing bending of the DNA, promotes protein-protein interaction and is able to activate downstream gene expression. An expectation for TDF was that mutations in its protein sequence would result in sex reversal. Examination of the *SRY* sequence in XY females has identified more than 50 mutations in the protein-coding sequence, with the majority located within the DNA-binding domain. Another prediction for TDF is that its presence can cause XX male sex reversal. The majority of XX males to date have been found to have Y chromosome segments containing *SRY*. This suggests a causative role of *SRY* in most cases of XX sex reversal. Therefore, genetic and molecular data have established that *SRY* can be equated to the TDF.

Additional insights have been gained regarding *SRY* function as a molecular switch that promotes testis development. *SRY* is expressed and functions in the supporting cells of the developing male urogenital ridge. These cells participate in cord formation and ultimately develop into Sertoli cells.

Figure 150-3. Diagram of the *SRY* (sex-determining region on the Y gene) locus, with the high-mobility group (HMG)-related box DNA-binding domain. Solid circles denote missense mutations that affect testicular development. Triangles indicate nonsense and frameshift mutations. (From Achermann JC, Hughes IA. Disorders of sex development. In: Melmed S, Polonsky KS, Larsen PR, et al, editors. Williams textbook of endocrinology. Philadelphia: Saunders; 2011.)

KEY POINTS: CHROMOSOMAL SEX

- Sinclair and colleagues (1990) discovered the TDF, a single-copy male-specific sequence that was evolutionarily conserved.
- This gene was termed *SRY* (sex-determining region Y gene) in humans and *Sry* in mice.

Additional Genes Involved in Gonadal Determination

Several additional genes involved in gonadal development have been identified and characterized. These include, but are not limited to, *WT1*, *NR5A1* (*SF1*), *SOX9*, *NR0B1* (*DAX1*), *WNT4*, *RSPO1*, and *FOXL2* (Fig. 150-4; Table 150-1). Newer data suggest that these factors function in defined but interrelated differentiation pathways during gonadal formation and determination.

WT1. The *WT1* gene was originally isolated in cloning experiments that identified an oncogene on human chromosome 11 as being involved in the development of Wilms tumor (Call et al, 1990). This gene, originally localized by examining chromosomal deletions in children with WAGR syndrome (Wilms tumor, aniridia, genitourinary abnormalities, gonadoblastoma, and mental retardation), was found to be expressed primarily in the kidney and gonads of the developing human embryo (Kreidberg et al, 1993). The first reported mutations in the Denys-Drash syndrome, which includes Wilms tumor, renal failure, and gonadal and genital abnormalities, were found to involve the *WT1* protein (Pelletier et al, 1991a, 1991b). Indeed, mutations involving *WT1* have been found to be responsible for both the Frasier and Denys-Drash syndromes, which appear to represent a spectrum of genetically induced abnormalities involving the gonads and kidneys, owing to the earlier involvement of *WT1* in the differentiation of both structures. Frasier syndrome is characterized by both gonadal dysgenesis and renal abnormalities that result in streak gonads and a nephrotic syndrome (MacLaughlin and Donahoe, 2004). If it occurs in the XY genotype, sex reversal results. As a result of alternative splicing of the *WT1* gene, patients with Frasier syndrome are not susceptible to Wilms tumor, whereas those with Denys-Drash syndrome are (Koziell and Grundy, 1999).

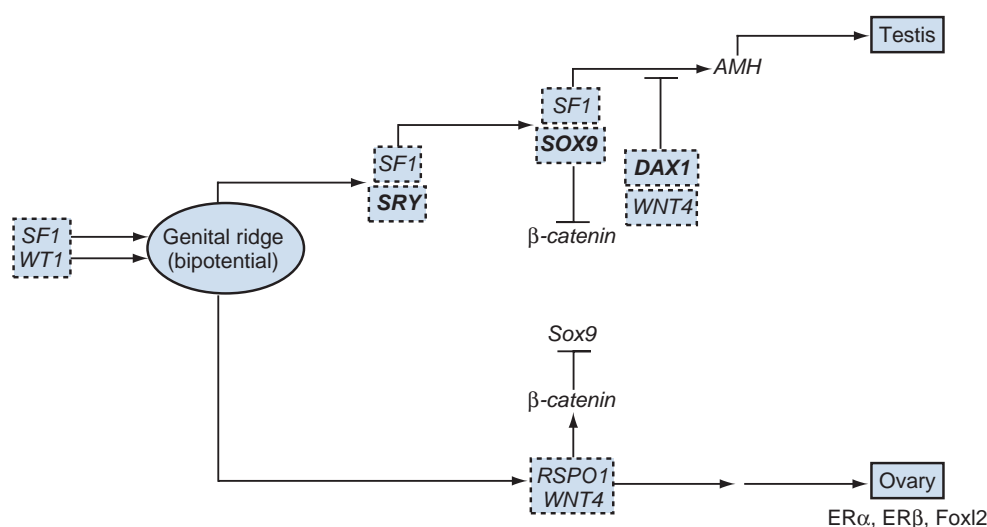

Figure 150-4. Genes determining testis or ovarian differentiation from bipotential gonad. *SF1* and *WT1* are essential for gonadal ridge formation and development. Gonadal determination is influenced by transient expression of the testis determination factor, *SRY*. *SOX9* upregulation by *SRY* leads to testis formation. Repression of *SOX9* by factors such as *DAX1* and *WNT4*/β-catenin results in inhibition of testis formation and promotion of ovarian development. (After Hughes IA. Intersex. *BJU Int* 2002;90:771; and Sekido R, Lovell-Badge R. Sex determination and *SRY*: down to a wink and a nudge? *Trends Genet* 2009;25[1]:19–29.)

TABLE 150-1 Loss of Function Phenotype (Human Data)

GENE	CHROMOSOME	46,XY	46,XX
<i>SRY</i>	Yp11.3	Female; gonadal dysgenesis (Swyer syndrome)	
<i>SOX9</i>	17q24.3-q25.1	Female; camptomelic dysplasia; ovaries to gonadal dysgenesis	Female; camptomelic dysplasia
<i>WT1</i>	11p13	Female; Wilms tumor; gonadal dysgenesis, mesangial sclerosis (Denys-Drash syndrome); streak gonads, glomerulosclerosis (Frasier syndrome)	Female; Wilms tumor; gonadal dysgenesis, mesangial sclerosis (Denys-Drash syndrome); streak gonads, glomerulosclerosis (Frasier syndrome)
<i>NR5A1 (SF1)</i>	9q33	Female; adrenal insufficiency; gonadal dysgenesis	
<i>NR0B1 (DAX1)</i>	Xp21.3-p21.2	Male; gonadal dysgenesis, hypogonadotropic hypogonadism; adrenal hypoplasia	
<i>WNT4</i>	1p36.23-p35.1		Male; aberrant müllerian structure development; wolffian development
<i>RSPO1</i>	1p34.3		Male; palmoplantar keratoderma; aberrant müllerian development; ovotestis
<i>FOXL2</i>	3q23		Female; blepharophimosis-ptosis-epicanthus inversus syndrome (BPES); premature ovarian failure (BPES type II)

In addition, with the Denys-Drash syndrome, gonads differentiate more completely than with Frasier syndrome. Research on *Wt1* in the mouse suggests that it exerts its effects upstream of *Sry* and is likely to be necessary for commitment and maintenance of gonadal tissue (Lim and Hawkins, 1998).

NR5A1 (SF1). Experiments in the mouse have demonstrated that nuclear receptor steroidogenic factor 1 (*SF1*) is expressed in all steroidogenic tissues, including adrenal cortex, testis (Leydig cells), ovarian theca, granulosa cells, and corpus luteum. *SF1* appears to be a key regulator of enzymes involved in steroid production, including the sex hormones, and may directly regulate pituitary gonadotropin expression (Parker et al, 2002). In addition, it appears to play a role in early gonadal development at multiple levels of the reproductive endocrine axis (Ingraham et al, 1994; Luo et al, 1994). *SF1* also appears to act synergistically with *WT1* in the regulation of müllerian-inhibiting substance expression (Shen et al, 1994; Imbeaud et al, 1995; Nachtigal et al, 1998) and may regulate *DAX1* (Yu et al, 1998) and *SOX9* expression (Sekido and Lovell-Badge, 2008).

SOX9. The *SOX9* gene was originally identified in patients with camptomelic dysplasia, a congenital disease of bone and cartilage formation that is often associated with XY sex reversal (Wagner et al, 1994). The *SOX9* gene is structurally quite similar to *SRY*, with a 71% sequence similarity of the HMG domain to that of *SRY*. Expression of the gene in adults is greatest in the testes. It is interesting to note that *SOX9* gene activity increases immediately after *SRY* expression, and cell lineage analyses show that *SOX9* protein is expressed in cells determined to become Sertoli cells (Sekido and Lovell-Badge, 2009). Therefore the *SOX9* gene may be a key downstream effector of *SRY* action. The activity of *SRY* on *SOX9* is synergistic with the activity of an additional transcription factor, *SF1*, which is essential for gonadal and adrenal development (Sekido and Lovell-Badge, 2008). A role for *SOX9* in male gonadal determination is further supported by data from genotypic males with *SOX9* mutations (46,XY) who exhibit ovarian development and male-to-female sex reversal (Foster et al, 1994; Wagner et al, 1994). *SOX9* also upregulates *AMH* gene expression (MacLaughlin and Donahoe, 2004).

NR0B1 (DAX1) and Dosage-Sensitive Sex Reversal (DSS). The first indication that an X-specific gene was involved in human sex

determination was provided in 1978 with the identification of a family with an X-linked mode of inheritance of 46,XY gonadal dysgenesis. Subsequent studies of a number of sex-reversed subjects confirmed the presence of additional X-chromosomal genetic material and a normal Y chromosome (Ogata et al, 1992). This finding suggested that duplication of an X-specific gene causes XY sex reversal by expressing a double dose of a region normally subject to X inactivation. Screening of XY females with a normal *SRY* gene detected such a submicroscopic duplication, involving a 160-kb region designated as the dosage-sensitive sex reversal (DSS) critical region (Bardoni et al, 1994). Parallel studies examining 46,XY males with gonadal dysgenesis, hypogonadotropic hypogonadism, and congenital adrenal hypoplasia resulted in the identification of a candidate gene, *NR0B1 (DAX1)*, within the DSS critical region (Muscatelli et al, 1994; Zanaria et al, 1994). It is interesting to note that *DAX1* can act to suppress or promote the testis determination pathway (Yu et al, 1998; Meeks et al, 2003). Although *DAX1* was initially believed to be the primary gene involved in DSS, several sex-reversed 46,XY patients have been identified with duplication of the DSS region in the absence of *DAX1* duplication, which suggests that the gene dosage effects of this region may be associated with an additional gene or genes (Zanaria et al, 1995).

WNT4. *WNT4* on chromosome 1p34 appears to be involved in müllerian duct regression and may also function by antagonizing *SRY* activity (Kim et al, 2006; Bernard and Harley, 2007). Early inactivation of *Wnt4* in mice causes failure of the formation of müllerian duct derivatives in both sexes. In addition, inactivation of *Wnt4* in female mice leads to wolffian duct development without testicular tissue formation and female external genitalia. Furthermore, a recent report supports the role of *WNT4* in development and maintenance of the female phenotype in women by regulating müllerian duct development and ovarian steroidogenesis (Biason-Laubier et al, 2004).

Rspo1. R-spondin-1 is encoded by the *Rspo1* gene. It belongs to a family of ligands that activate the Wnt and β -catenin signaling pathways. Expression of R-spondin-1 overlaps that of Wnt in many tissues and can synergize with Wnt by stabilizing cytoplasmic β -catenin. The *Rspo1* gene was identified as a candidate gene in ovarian determination by linkage analysis of a large consanguineous

Figure 150-5. Migration of primordial germ cells. At 3 weeks, primordial germ cells (PGCs) are being formed and migrate along the wall of the yolk sac to reach the caudal part of the fetus. By 5 weeks, they have reached the level of the gonadal ridges (GRs). (Modified from DeFelici M. Origin, migration, and proliferation of human primordial germ cells. In: Coticchio G, Albertini DF, DeSantis L, editors. *Oogenesis*. London: Springer-Verlag; 2013. p. 21.)

Italian family with cosegregation of palmoplantar hyperkeratosis (PPK) trait and XX female-to-male sex reversal (Parma et al, 2006). A single nucleotide, frameshift mutation was found in affected individuals from the consanguineous family and deletion mutations in sporadic cases of PPK and XX sex reversal.

Normal Phenotypic Development

Gonadal Stage of Differentiation

During the first 6 weeks of embryonic development, the gonadal ridge, germ cells, internal ducts, and external genitalia are bipotential in both 46,XY and 46,XX embryos. Under the genetic influences of sex determination, the bipotential gonadal ridges differentiate into either ovaries or testes, and germ cells develop into either oocytes or spermatocytes. Primordial germ cells can be recognized in the third week of gestation on the posterior wall of the secondary yolk sac. Migration of the germ cells begins in the fifth week of gestation from the dorsal wall of the yolk sac through the mesentery to the medial ventral aspect of the urogenital ridge (DeFelici, 2013) (Fig. 150-5). This process is dependent on chemoattractants and cell adhesion molecules (Hughes, 2002). Overall, a population of 1000 to 2000 primordial germ cells reaches the gonadal blastema by the sixth week of gestation.

Transformation of the germ cells into spermatogonia and oogonia results from differentiation of the epithelial gonadal compartments referred to as testicular and ovarian "cords." *SRY* initiates the switch that induces a cascade of genes directing the indifferent gonad toward testicular organogenesis. The precise moment at which this occurs remains unknown. Initially, differentiation of Sertoli cells is noted as testicular cords form at 6 to 7 weeks' gestation, creating the basement membrane, or blood-testis barrier, of spermatogonia and Sertoli cells on one side and mesenchymal fibroblasts on the other. The differentiation of Sertoli cells is associated with the production of MIS, a glycoprotein encoded by a gene on the short arm of chromosome 19 (Haqq et al, 1994). In males, a second line of primordial cells of steroidogenic mesenchyme remain among the testicular cords and represent future Leydig cells, which differentiate at 8 to 9 weeks. In the absence of *SRY*, ovarian organogenesis results. Little is known about the genetic control of ovarian development. To date, no genes whose products direct development of the ovary have been identified. It does appear necessary that there be duplicate copies of at least one X-chromosomal locus (which presumably explains the dys-

genetic ovaries in the 45,XO Turner syndrome patients). A potential candidate may lie within the DSS critical region on Xp-21, which, when duplicated, promotes male-to-female "sex reversal" (Bardoni et al, 1994; Lopez et al, 1998).

Unlike the testis, which functions primarily as a fetal endocrine organ, the ovary has primarily exocrine activity. In embryonal ovaries, germ cells undergo intense mitotic proliferation (preceding the onset of meiotic prophase) and in the process exhaust their entire mitotic potential prenatally, reaching a maximum endowment of 20 million cells by 20 weeks' gestation. The presence of two X chromosomes appears to be responsible for differentiation of the granulosa cells into the protective mantle of the granulosa layer and "rescue" of 30% of germ cells (approximately 2 million) (Byсков and Westergaard, 1998).

KEY POINT: GONADAL STATE OF DIFFERENTIATION

- During the first 6 weeks of embryonic development the gonadal ridge, germ cells, internal ducts, and external genitalia are bipotential in both 46,XY and 46,XX embryos.

Gonadal Function

Testis

The initial endocrine function of the fetal testes is the secretion of MIS by the Sertoli cells at 7 to 8 weeks' gestation. MIS, one of the two hormones necessary for male sexual differentiation, acts locally to produce müllerian regression. It is a member of the transforming growth factor- β (TGF- β) family, and the human gene has been cloned and mapped to chromosome 19 (Cate et al, 1986). Little is known about the cellular mechanism of action of MIS. Because the hallmark of MIS-mediated müllerian duct regression is the formation of a ring of connective tissue around the epithelial cells, it is likely that the mesenchyme is the primary target of MIS. Testosterone secretion by the fetal testes is detectable shortly after the formation of Leydig cells in the interstitium at approximately 9 weeks' gestation (Siiteri and Wilson, 1974). There is a rise in serum and testicular testosterone to a peak concentration at 13 weeks and then a decline. The rate-limiting enzyme for fetal testosterone synthesis is 3 β -hydroxysteroid dehydrogenase, which is concentrated approximately 50 times more highly in the fetal testes

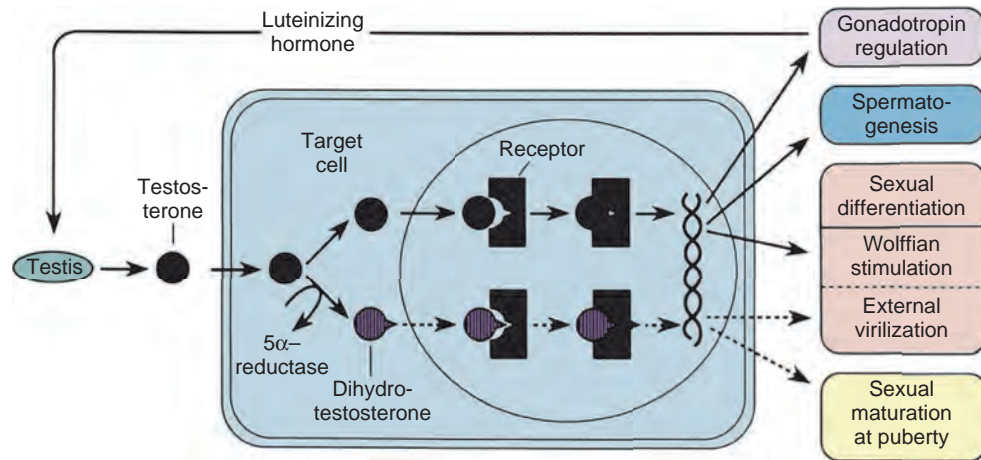

Figure 150-6. Schematic diagram of normal androgen physiology. The major actions of androgens are listed on the right. Testosterone enters androgen target tissues and either binds to the androgen receptor in cell nuclei or is converted by 5 α -reductase to dihydrotestosterone (DHT). DHT binds to the same receptor but with greater affinity. Androgen actions mediated by testosterone are indicated by solid arrows, and those mediated by DHT are indicated by dashed arrows. (From Griffin JE, Wilson JD. Syndromes of androgen resistance. *Hosp Pract* 1987;22:99–114.)

than in the ovary. Androgens are synthesized by the Leydig cells, initially autonomously, but then dependent on placental human chorionic gonadotropin (hCG) secretion. Later in gestation, with declining hCG concentrations, androgen synthesis is controlled by luteinizing hormone (LH) secretion by the fetal pituitary gland. [Jost and colleagues \(1973\)](#) clearly demonstrated that androgen is essential for virilization of wolffian duct structures, the urogenital sinus, and the genital tubercle. Testosterone, the major androgen secreted by the testes, enters target tissues by passive diffusion. Organs such as the wolffian duct, adjacent to the fetal testis, also take up testosterone by pinocytosis. The local source of androgen is important for wolffian duct development, which does not occur if testosterone is supplied only via the peripheral circulation. In some cells, such as those in the urogenital sinus, testosterone is converted to dihydrotestosterone (DHT) by intracellular 5 α -reductase. Testosterone or DHT then binds to a high-affinity intracellular receptor protein, and this complex enters the nucleus, where it binds to acceptor sites on DNA, resulting in new messenger RNA and protein synthesis ([Fig. 150-6](#)). The androgen receptor has been characterized as a high-affinity receptor that mediates the action of testosterone and DHT in all androgen-dependent tissues. In disorders of the androgen receptor, such as androgen insensitivity syndrome, testosterone production is normal but the hormone is unable to reach the nucleus and interact with DNA. Various defects in the androgen receptor result in a spectrum of phenotypic abnormalities in the genetic male. Because gonadal females have androgen receptor within their tissues, exogenous androgen produces virilization. DHT binds to the androgen receptor with greater affinity and stability than does testosterone. Therefore, in tissues equipped with 5 α -reductase at the time of sexual differentiation (e.g., prostate, urogenital sinus, external genitalia), DHT is the active androgen ([George and Peterson, 1988](#)). The 5 α -reductase activity has two optimal pH values in cultured genital skin fibroblasts—one at pH 5.5 and a second one near pH 8—that correspond to two distinct enzymes ([Jenkins et al, 1992](#)). The alkaline enzyme human steroid 5 α -reductase type 1 was cloned first; however, the primary enzyme in the prostate is 5 α -reductase type 2 ([Andersson and Russell, 1990](#)). A deletion in the gene coding for this enzyme has been discovered in intersex patients with 5 α -reductase deficiency ([Andersson et al, 1991](#)). The gene encoding the androgen receptor has been cloned and mapped to the X chromosome at Xq11-12 ([Lubahn et al, 1988](#)).

KEY POINT: GONADAL FUNCTION

- DHT binds to the androgen receptor with greater affinity and stability than does testosterone. Therefore in tissues equipped with 5 α -reductase at the time of sexual differentiation (e.g., prostate, urogenital sinus, external genitalia), DHT is the active androgen.

Ovary

Estrogen synthesis is detectable in the female embryo just after 8 weeks of gestation. The rate-limiting enzyme is aromatase, which is higher in the fetal ovary than in the fetal testis. Estrogens are not required for normal female differentiation of the reproductive tract, but they can interfere with male differentiation. Estrogen can block the effect of MIS on müllerian ducts, and prenatal estrogen treatment of mothers has been associated with male reproductive tract abnormalities ([Gill et al, 1979](#); [Vigier et al, 1989](#)).

Phenotypic Sexual Differentiation

Before the 8th week of gestation the urogenital tract is identical in the two sexes. Both the wolffian and the müllerian duct systems are present as anlagen of the internal accessory organs of reproduction ([Fig. 150-7](#)). In addition, at this stage the anlagen of the external genitalia of male and female embryos are indistinguishable ([Fig. 150-8](#)). In the male fetus, Sertoli cells produce MIS, which acts locally and unilaterally to suppress the müllerian ducts, and Leydig cells produce testosterone, which permits local development of the wolffian ducts. By 10 weeks of gestation, degeneration of the müllerian ducts is almost complete and the wolffian ducts have become more prominent (see [Fig. 150-7](#)). Adjacent to the testes, convolutions of the ducts organize to form the epididymis. The wolffian ducts of the epididymis join with the collecting portion of the testicular tubules (rete testis). Distally, the ducts join the urogenital sinus by about 30 days' gestation, where they develop into the seminal vesicles. In the female fetus, testosterone is not secreted by the ovaries and therefore the wolffian ducts regress. Because the ovary does not produce MIS, the müllerian ducts are

maintained and develop into the female internal reproductive tract. The cephalic ends are anlagen of the fallopian tubes, and the caudal ends fuse to form the uterus (see Fig. 150-7). Contact of the müllerian ducts with the urogenital sinus induces formation of the uterovaginal plate, which ultimately forms the lumen of the vagina. The relative contributions of the müllerian ducts and urogenital

sinus to the formation of the vagina remain somewhat controversial; however, there is some agreement that the proximal two thirds of the vagina is contributed by the müllerian ducts and the distal one third by the urogenital sinus. Masculinization of the male fetus starts at 7 to 8 weeks of gestation (Fig. 150-9). The first sign of male phenotypic differentiation is degeneration of the müllerian ducts adjacent to the testes as a result of MIS secretion by the Sertoli cells. Whereas the effects of androgen on the wolffian ducts are related to diffusion of testosterone from the adjacent gonad, masculinization of the external genitalia results from the systemic delivery of testosterone with local conversion to DHT. By 10 weeks, an increase in distance between genital tubercle and anal folds can be seen. The genital tubercle thickens and elongates to become the penis, and the urethral folds fuse from posterior to anterior over the urethral groove (Fig. 150-10). Near the bladder, the urethra is surrounded by the prostate. The urogenital swellings migrate posteriorly to the genital tubercle and fuse to form the scrotum. By 12 to 13 weeks' gestation, the genitalia of the male fetus are completed with closure of the elongated urogenital cleft. Under the influence of androgen secreted by the fetal testes, penile growth and testicular descent occur in the third trimester (see Fig. 150-9). In the female fetus the absence of circulating testosterone maintains the appearance of the external genitalia at the 6-week gestational stage. The genital tubercle develops only slightly to form the clitoris. The lateral genital swellings become the labia majora, and the adjacent urethral folds become the labia minora (Fig. 150-11). Between the labia minora will develop the vaginal introitus and urethral meatus.

Figure 150-7. Differentiation of the wolffian and müllerian duct and urogenital sinus in the male and female. (From Wilson JD. *Embryology of the genital tract*. In: Harrison HH, Gittes RF, Perlmutter AD, et al, editors. *Campbell's urology*. 4th ed. Philadelphia: Saunders; 1979. p. 1473.)

Gender Identity, Gender Role, and Gender Orientation

Psychosexual Differentiation

Humans have been recognized as having sexually dimorphic behavior, which has several aspects: (1) *gender identity*, the identification of self as either male or female; (2) *gender role*, aspects of behavior in which males and females appear to differ; (3) *gender orientation*, or choice of sexual partner (heterosexual, homosexual, or bisexual); and (4) *cognitive differences* (Grumbach and Conte, 1998). Gender identity is a complex and poorly understood phenomenon in humans, and the mechanisms appear multifactorial. Experience in patients with congenital adrenal hyperplasia (CAH) who were exposed prenatally to androgen and in patients reared in a sex

Figure 150-10. Schematic diagram of differentiation of the male external genitalia. (From Martinez-Mora J. Development of the genital tract. In: Martinez-Mora J, editor. *Intersexual states: disorders of sex differentiation*. Barcelona: Ediciones Doymer; 1994. p. 53.)

Figure 150-11. Schematic diagram of differentiation of the female external genitalia. (From Martinez-Mora J. Development of the genital tract. In: Martinez-Mora J, editor. *Intersexual states: disorders of sex differentiation*. Barcelona: Ediciones Doymer; 1994. p. 52.)

opposite to their chromosomal or gonadal sex have provided evidence to indicate that gender identity is not merely a function of chromosomal complement or prenatal endocrine milieu. Postnatal environmental factors and learning appear to have an important effect. However, strong evidence has accumulated for the impact of prenatal hormonal influences on sexually dimorphic behavior or gender role. For example, long-term follow-up with CAH patients has supported a greater interest in “tomboyish behavior” than in unaffected girls, although these patterns are not abnormal in relation to female behavior in Western society (Ehrhardt and Meyer-Bahlburg, 1981). Additional information regarding the influence of androgens on gender identity and gender role has arisen from one study of males with cloacal exstrophy who underwent gender reassignment within the first few months of life. A majority of these patients had behaviors and attitudes that reflected strong male-typical characteristics regardless of whether they were raised as males or females (Reiner and Gearhart, 2004). However, a subsequent British study of a similar 46,XY cloacal exstrophy cohort presented contradictory findings (Baker Towell and Towell, 2003). The previously accepted dogma that children are psychosexually neutral at birth and capable of being environmentally oriented (the blue room/pink room theory) has been seriously challenged by those who support the concept of prenatal psychosexual differentiation (Money and Ehrhardt, 1972; Diamond and Sigmundson, 1997). Support for either theory in humans is based on the assessment of a limited number of affected patients. An improved understanding of the “nature versus nurture” controversy will probably prove important in the optimal management of patients with DSDs. However, our increased awareness of physiologically normal patients with genuine “gender dysphoria” has illustrated the complexity of this process.

KEY POINT: PSYCHOSEXUAL DIFFERENTIATION

- The previously accepted dogma that children are psychosexually neutral at birth and capable of being environmentally oriented (the blue room/pink room theory) has been seriously challenged by those who support the concept of prenatal psychosexual differentiation.

ABNORMAL SEXUAL DIFFERENTIATION

The classification of DSDs (previously *intersex disorders*) has undergone evolutionary change as understanding of the etiologic mechanisms of normal and abnormal sexual differentiation has improved. As a result, classification systems vary. We have borrowed from the system used by Grumbach and Conte (1998), which incorporates the historical emphasis on classification by gonadal morphology, and introduced more contemporary terminology (Hughes et al, 2006). Descriptive terms for abnormal gonadal histology have been retained, with the exception of *true hermaphroditism*, which has been replaced by *ovotesticular DSD*. However, for masculinized 46,XX females with two ovaries, *female pseudohermaphroditism* has been replaced by 46,XX DSD; and for undermasculinized 46,XY males the term *male pseudohermaphroditism* has been replaced by 46,XY DSD. The first category consists of disorders of gonadal differentiation; the second includes ovotesticular DSD; the third includes 46,XX DSD (the masculinized female, that is, ovaries present but external genitalia exhibiting evidence of masculinization); the fourth includes 46,XY DSD (the undermasculinized male, that is, testes present but genital ducts and/or external genitalia incompletely masculinized); and the fifth category consists of unclassified forms. Within each category, remarkable advances in chromosomal and biochemical information have allowed subclassification of disorders based on etiologic mechanisms, contributing to a more rational classification system (Box 150-1).

BOX 150-1 Abnormal Sexual Differentiation

1. Disorders of gonadal differentiation
 - Seminiferous tubule dysgenesis
 - Klinefelter syndrome
 - 46,XX male
 - Syndromes of gonadal dysgenesis
 - Turner syndrome
 - Pure gonadal dysgenesis
 - Mixed gonadal dysgenesis
 - Partial gonadal dysgenesis (dysgenetic male pseudohermaphroditism)
 - Bilateral vanishing testis, testicular regression syndromes
2. Ovotesticular DSD (true hermaphroditism)

DSD, disorder of sex development.

Disorders of Gonadal Differentiation and Development

Klinefelter Syndrome and Variants

In 1942, Klinefelter, Reifenstein, and Albright described a syndrome characterized by eunuchoidism, gynecomastia, azoospermia, increased gonadotropin levels, and small, firm testes. By 1959, these patients were noted to have a 47,XXY karyotype (Jacobs and Strong, 1959).

Klinefelter syndrome represents the most common major abnormality of sexual differentiation. By definition, males with at least one Y chromosome and at least two X chromosomes have Klinefelter syndrome. The classic 47,XXY complement arises as a result of nondisjunction during meiosis; it occurs in 1 of 600 live-born males (Morris et al, 2008). But the phenotype is also associated with 48,XXYY and 49,XXXYY, and an exaggerated form of the phenotype is associated with 48,XXXY and 49,XXXXY. The mosaic form

46,XY/47,XXY is associated with a milder version of the phenotypic features of classic 47,XXY Klinefelter syndrome. Perhaps as a result of phenotypic variability, Klinefelter syndrome is believed to be underdiagnosed, with a 25% diagnostic rate in one Danish study (Bojesen et al, 2004).

In 47,XXY adults, seminiferous tubules degenerate and are replaced with hyaline. As a result, testes are firm and small, less than 3.5 cm in length. Histologically, Leydig cells appear to be present in large numbers because they are seen in large clumps in certain areas of the testes, sometimes resembling Leydig cell tumors. However, the absolute volume of Leydig cells is not increased and is probably lower than normal. Serum levels of testosterone are low-normal and those of gonadotropins are elevated. Plasma estradiol levels tend to be high, with gynecomastia the result of an increased ratio of estradiol to testosterone. The vast majority of patients are azoospermic, and the presence of sperm suggests 46,XY/47,XXY mosaicism. There does appear to be a depletion of germ cells with the onset of puberty (Wikström et al, 2004). Fertility, with the benefit of testicular sperm extraction (TESE) and intracytoplasmic sperm injection, has been reported in patients with Klinefelter syndrome (Koga et al, 2007). Some infertility experts advocate coupling intracytoplasmic sperm injection with preimplantation diagnosis, given the lower rate of normal embryos from Klinefelter syndrome patients (54%) versus controls (77%) (Staessen et al, 2003).

The decreased androgen production may impair normal secondary sexual development. Muscle development may be poor, and the fat distribution is more female than male. Normal amounts of pubic and axillary hair may be present, but facial hair is sparse. Patients tend to be taller than average, mainly because of the disproportionate length of their legs, which is present even in childhood. Otherwise, few if any distinguishing features are present in the prepubertal child.

Gynecomastia, which can be quite marked, is a common pubertal development in patients with Klinefelter syndrome. As a result, these patients have eight times the risk for development of breast carcinoma compared with normal males (Hamden et al, 1971). In addition, they are predisposed to developing malignant neoplasms of extragonadal germ cell origin as well as Leydig and Sertoli cell tumors (Völkl et al, 2006). Therefore, routine surveillance scrotal ultrasonography has been advocated for postpubertal patients with Klinefelter syndrome.

An intriguing area of research has been in the neuropsychiatric function of Klinefelter syndrome patients. Studies have demonstrated depressed verbal ability and limitations in frontal executive functioning. Recent imaging studies have shown selective volume differences in corresponding areas of Klinefelter syndrome patients' brains versus those of normal subjects (Giedd et al, 2007). Other studies have demonstrated altered cerebral perfusion in Klinefelter syndrome, corresponding to impaired verbal skills (Itti et al, 2003).

Management of Klinefelter syndrome entails careful androgen supplementation in selected male patients to improve libido and reduction mammoplasty if necessary. Surveillance for testicular tumor and breast carcinoma is also appropriate. Assisted reproductive techniques now offer potential fertility to nonmosaic Klinefelter syndrome patients. Microdissection testicular sperm extraction (micro-TESE) results in sperm retrieval rates in the 40% to 50% range, with higher rates in younger men (Bryson et al, 2014). Research efforts to determine whether sperm retrieval rates are higher in adolescent males than in adult males are ongoing.

46,XX Males

The condition of 46,XX maleness, which occurs in 1 of every 20,000 males, may be closely related to that of Klinefelter syndrome. Historically, the genetic analysis of subjects with sex reversal who had a phenotypic sex different from that anticipated based on karyotype was crucial for identification of the SRY gene.

XX maleness, first recognized by de la Chappelle and coworkers in 1964, is characterized by testicular development in subjects

who have two X chromosomes and lack a normal Y chromosome. Most of these subjects have normal male external genitalia, but 10% have hypospadias and all are infertile. Among infertile adults, 2% have XX maleness (Van Dyke et al, 1991).

Two categories of patients with XX maleness have been identified: the 90% who are SRY positive and those who are SRY negative (Ergun-Longmire et al, 2005). The SRY-positive group rarely have genital abnormalities, but they have phenotypic features of Klinefelter syndrome, including hypogonadism, gynecomastia, azoospermia, and hyalinization of seminiferous tubules with altered hormonal levels at puberty (low testosterone, increased follicle-stimulating hormone [FSH] and LH) (Fechner et al, 1993). Often the diagnosis is made in a pubertal male who is seen for evaluation of gynecomastia. **These patients differ from those with Klinefelter syndrome in that they are shorter (mean height, 168 cm) and have normal skeletal proportions.** The 10% of XX males with no detectable SRY more commonly have genital ambiguity.

Three mechanisms have been proposed to explain XX sex reversal. **The most common is translocation of Y-chromosomal material, including SRY, to the X chromosome.** Clearly, this can be proven in the majority of patients. Alternatively, sex reversal could result either from the mutation of an autosomal or X-chromosomal gene, permitting testicular differentiation downstream from SRY, or from undetected mosaicism with a Y-bearing cell line. Clinical studies have demonstrated XX sex reversal to be a genetically and phenotypically heterogeneous condition (Fechner et al, 1993).

Treatment of XX maleness is similar to that for Klinefelter syndrome. Androgen replacement benefits selected patients, and reduction mammoplasty may be beneficial. It is likely that these patients will also be at increased risk for breast carcinoma and testis tumor. Because of their lack of germ cell elements, those classic patients with infertility would not benefit from testicular biopsy for potential intracytoplasmic sperm injection.

Syndromes of Gonadal Dysgenesis

Turner Syndrome. In 1938, Henry Turner described the combination of sexual infantilism, webbed neck, and cubitus valgus (increased carrying angle at the elbows) as a distinct entity. Subsequently, gonadal dysgenesis was recognized as part of this syndrome (Hall and Gilchrist, 1990). It was not until 1959 that Ford recognized that one missing X chromosome was the etiologic basis for the syndrome. Subsequent chromosomal studies showed that **Turner syndrome is characterized by the presence of only one normally functioning X chromosome.** The other sex chromosome may be absent or abnormal, or mosaicism may be present.

Turner syndrome, with a 45,X karyotype, is associated with four classic features: female phenotype, short stature, lack of secondary sexual characteristics, and a variety of somatic abnormalities. However, the clinical features of Turner syndrome are quite variable, and almost any combination of physical features may be seen with any X-chromosomal abnormality. The severity of phenotypic features does not necessarily correlate with karyotypic findings. The diagnosis of Turner syndrome should be considered in any infant with lymphedema or any young woman with short stature or primary amenorrhea. Deletions in the short stature homeobox gene (*SHOX*) located on the pseudoautosomal region of the X and Y chromosomes have been suggested as the basis for the short stature in this syndrome.

Turner syndrome has an incidence of 1 in 2500 live births. Half of the patients have a 45,X karyotype in all cells; this is believed to be secondary to loss of an X chromosome through nondisjunction in gametogenesis or an error in mitosis. From 12% to 20% of patients with Turner syndrome have an isochromosome X (duplication of one arm of the X chromosome with loss of the other arm). Mosaicism—the presence of two or more chromosomally different cell lines—occurs in 30% to 40% of these patients, the majority (10% to 15%) being 45,X/46,XX and 2% to 5% being 45,X/46,XY (Zinn et al, 1993). **The presence of Y-chromosomal material is of critical importance in patients with Turner**

syndrome because it predisposes them to potential masculinization and gonadoblastoma.

Turner syndrome may be diagnosed prenatally on the basis of a variety of ultrasound findings (increased nuchal translucency, lymphedema, cystic hygroma, coarctation of the aorta, renal anomalies) or by abnormal results of fetal karyotyping. Affected fetuses often abort spontaneously. Whereas a 45,X fetus identified prenatally has a prognosis similar to that of a child with Turner syndrome diagnosed postnatally, approximately 90% of fetuses in whom a 45,X/46,XX or 45,X/46,XY karyotype is incidentally diagnosed prenatally will have a normal female or male phenotype at birth. This so-called ascertainment bias in Turner syndrome has profound implications for prenatal counseling.

It is postulated that in Turner syndrome follicular cells that normally surround the germ cells and provide a protective mantle for the oocytes are inadequate (Stanhope et al, 1992). As a result, the rate of attrition of oocytes from apoptosis is so rapid that by birth few or no oocytes remain in the ovaries, which become streaks (Epstein, 1990). Typically, these streaks are white, fibrous structures, 2 to 3 cm long and approximately 0.5 cm wide, located in the broad ligament. Histologically, the streak possesses interlacing waves of dense fibrous stroma that is devoid of oocytes but is otherwise indistinguishable from normal ovarian stroma. Both estrogen and androgen are decreased, and levels of FSH and LH are increased. Secondary sexual development does not occur in the majority of patients. Pubic and axillary hair fails to develop in normal abundance, and the well-differentiated external genitalia, vagina and müllerian derivatives, and breasts remain small (Saenger, 1996). Turner syndrome is a common cause of primary amenorrhea, and the diagnosis is frequently made because pubertal development never occurs. Spontaneous pubertal development may occur in up to 30% of Turner syndrome patients, however.

The associated congenital anomalies that are thought typical in Turner syndrome include short stature, broad chest, widespread nipples, webbing of the neck, peripheral edema at birth, short fourth metacarpal, hypoplastic nails, multiple pigmented nevi, coarctation of the aorta, bicuspid aortic valve, and renal anomalies (Fig. 150-12). The majority of the associated congenital anomalies can be explained by the presence of lymphedema at critical points in development, leading to an imbalance in growth forces. This may be secondary to failed opening of embryonic lymphatic channels (Zinn et al, 1993).

Of paramount importance in the assessment of the patient with Turner syndrome is identification of Y-chromosomal material or

45,X/46,XY mosaicism, whose detection has been enhanced by use of the polymerase chain reaction (PCR) (Bianco et al, 2006). In patients with occult Y-chromosomal material, the risk of gonadoblastoma, an *in situ* germ cell cancer, is 12% and is being further defined (Schoemaker et al, 2008). Gonadoblastoma is associated with dysgerminoma or other germ cell neoplasms in 50% to 60% of patients, sometimes associated with virilization. Because the age of occurrence of gonadoblastoma is variable and has been reported as early as age 10 months (Palmer, personal communication, 2013), timely prophylactic excision of the streak gonads in the Y mosaic Turner syndrome patient is advised. This may be well performed laparoscopically. Streak gonads confirmed to be in 45,XO patients need not be removed. In the recent British national cohort study there was also an increased risk of bladder and urethral cancer in Turner syndrome patients followed into adulthood (Schoemaker et al, 2008).

From 33% to 60% of patients with Turner syndrome have structural or positional abnormalities of the kidney; this occurs most frequently in the classic 45,XO karyotype (Hall and Gilchrist, 1990). Horseshoe kidney accounts for 10%, duplication or renal agenesis for 20%, and malrotation for 15% of these abnormalities. Multiple renal arteries have been noted in 90% of patients with Turner syndrome as a result of their cardiovascular evaluation (Hall and Gilchrist, 1990).

The contemporary treatment of patients with Turner syndrome has undergone considerable advances. In the neonate, it entails a concerted search for occult Y-chromosomal material, including fluorescence *in situ* hybridization (FISH) or PCR and, subsequently, prophylactic gonadectomy if necessary, as well as ultrasound screening for renal and cardiac abnormalities. In the child, human growth hormone has successfully been used to achieve increased adult height (Pasquino, 2004). At an appropriate age, typically 12 to 15 years, exogenous hormonal therapy to induce puberty and then to maintain a normal female endocrine status is begun. An improved understanding of the long-term medical management of these patients, including cardiac surveillance and management of glucose intolerance and osteoporosis, has also resulted in considerable progress. Finally, with the remarkable advances in assisted reproductive technology, pregnancy is a realistic possibility for patients with Turner syndrome, although spontaneous fertility is rare (Sybert and McCauley, 2004). A spectrum of potential gonadal function has been noted in large series of patients with Turner syndrome (Kaneko et al, 1990). In one series, nonstreak gonads were reported in one third of such patients and were more commonly noted in girls with loss of only the short arm of the X chromosome. In 2% to 5% of Turner patients, spontaneous menses will occur with a potential to achieve pregnancy independently (Saenger et al, 2001). This appears most likely in women with mosaicism for a normal 46,XX cell line, a 47,XXX cell line, or distal Xp deletion. To date, more than 160 pregnancies have been reported among spontaneously menstruating Turner syndrome patients. For the vast majority with true streak gonads, for whom egg donor implantation is used, 40% to 50% pregnancy rates have been reported by centers specializing in *in vitro* fertilization (Saenger, 1993). However, among these rare pregnancies, the rates of miscarriage, stillbirth, and malformed infants are high (Abir et al, 2001). Because of a high likelihood of premature ovarian failure, early oocyte preservation may be useful for long-term fertility preservation. Techniques for mature oocyte cryopreservation have dramatically improved, resulting in a recent guideline stating that the technology should no longer be considered experimental (Practice Committees of the American Society for Reproductive Medicine and the Society for Assisted Reproductive Technology, 2013). However, the risk of chromosomal abnormalities and unknown efficacy of oocyte preservation in this population require further investigation.

It is of great interest that neuroanatomic imaging studies of 45,XO Turner syndrome patients have demonstrated differences in parietal and temporal lobe anatomy and posterior fossa morphology that appear to correlate with certain established neurophysiologic and cognitive deficits (Brown et al, 2004; Rae et al, 2004).

Figure 150-12. Patient with Turner syndrome as originally described by Ullrich in 1930. (From Ullrich O. Über typische Kombinationsbilder multipler Abartungen. *Z Kinderheilkd* 1930;49:271–76.)

KEY POINTS: TURNER SYNDROME

- In patients with Turner syndrome and occult Y-chromosomal material, the risk of gonadoblastoma, an in situ germ cell cancer, is 12% and is being further defined.
- Young women with Turner syndrome and spontaneous menses are at high risk for premature ovarian failure. Mature oocyte cryopreservation is now an option.

46,XX “Pure” Gonadal Dysgenesis. Patients with 46,XX “pure” gonadal dysgenesis are characterized by normal female external genitalia, normal müllerian ducts with absence of wolffian duct structures, a normal height, bilateral streak gonads, sexual infantilism, and a normal 46,XX karyotype. The streak gonads result in elevated serum gonadotropins. Because these subjects exhibit none of the somatic stigmata associated with Turner syndrome and their condition entails gonadal dysgenesis only, it has been regarded by some authors as “pure.”

A familial incidence of 46,XX gonadal dysgenesis has been reported as an autosomal recessive trait (Espinosa et al, 1970). This suggests the possibility that autosomal genes in addition to genes on the X chromosome may be involved in ovarian maintenance.

Management of patients with 46,XX pure gonadal dysgenesis entails proper cyclic hormone replacement with estrogen and progesterone. In contrast to Turner syndrome, growth is not abnormal with this condition, and therefore growth hormone should not be required. Because, by definition, these patients have no Y-chromosomal material, gonadectomy is not required.

Mixed Gonadal Dysgenesis. The term *mixed gonadal dysgenesis* was coined by Sohval in 1963. In 1975, Zah and associates reported on their series of more than 100 patients with 45,X/46,XY karyotypes, 72 of whom had mixed gonadal dysgenesis with a streak gonad on one side and a testis on the other.

Mixed gonadal dysgenesis is characterized by a unilateral testis, which is often intra-abdominal, a contralateral streak gonad, and persistent müllerian structures associated with varying degrees of inadequate masculinization. Most patients with mixed gonadal dysgenesis have a 45,XO/46,XY karyotype, which is probably the result of anaphase lag during mitosis. The 45,X/46,XY mosaicism is the most common form of mosaicism involving the Y chromosome.

The phenotypic spectrum of patients with XO/XY mosaicism ranges from phenotypic females with Turner syndrome, to those with ambiguous genitalia, to those with normal male genitalia (Johansen et al, 2012). In the neonatal period, mixed gonadal dysgenesis is the second most common cause of ambiguous genitalia (after CAH) and must be in the differential diagnosis. The majority of these patients have varying degrees of phallic development, a urogenital sinus with labioscrotal fusion, and an undescended testis. In virtually all of these patients, a uterus, vagina, and fallopian tube are present. Short stature and associated somatic stigmata are variable features.

KEY POINT: MIXED GONADAL DYSGENESIS

- In the newborn period, mixed gonadal dysgenesis is the second most common cause of ambiguous genitalia (after CAH) and must be in the differential diagnosis.

The phenotypic asymmetry of the internal ducts epitomizes the mechanism of local testosterone and MIS production on müllerian and wolffian duct regression and development. In the series of Mendez and colleagues (1993) consisting of 16 patients, all had a fallopian tube accompanied by a streak gonad, consistent with

absent MIS. Therefore, whereas a dysgenetic or streak gonad is associated with ipsilateral müllerian derivatives (uterus, fallopian tube) (Fig. 150-13), a well-differentiated testis with functional Sertoli and Leydig cells will have ipsilateral wolffian but no müllerian ducts (Davidoff and Federman, 1973). In addition, the presence of severe external genital ambiguity in many of these patients suggests that testosterone production in utero was inadequate to promote complete differentiation of the external genitalia. Paradoxically, the dysgenetic testis is capable of responding to gonadotropins and secreting testosterone in normal quantities at puberty. Yet, despite normal postpubertal endocrine function, it is postulated that fetal testicular endocrine function is either delayed or deficient. Histologically, the testes lack germinal elements, so infertility is the rule.

The risk of developing a gonadal tumor (gonadoblastoma, dysgerminoma) is increased in mixed gonadal dysgenesis, with an estimated incidence of 15% to 35% (Robboy et al, 1982; Wallace and Levin, 1990). Gonadoblastoma, a tumor of low malignant potential, is the most common. It was so named because it recapitulates gonadal development more completely than any other tumor (Scully, 1970). Although germ cell tumors occur both in the dysgenetic testes and in the streak gonads of individuals with 46,X/46,XY mosaicism, the risk of tumor is higher in the former (Verp and Simpson, 1987).

Patients with mixed gonadal dysgenesis are also at increased risk for Wilms tumor. Rajfer (1981) reported that 50% of 10 patients with an intersex disorder and Wilms tumor had mixed gonadal dysgenesis. He postulated that there was a genetic or teratogenic defect involving the urogenital ridge, the common embryonic anlage of both kidney and gonad. This concept was borne out by improved understanding of the Denys-Drash syndrome, now clearly associated with mutations in the Wilms tumor suppressor gene (*WT1*). In 1967, Denys and colleagues described a child with XX/XY mosaicism, nephropathy, genital abnormalities, and Wilms tumor. Drash and coworkers (1970) reported two further examples in 1970. The full triad of the syndrome includes nephropathy, characterized by the early onset of proteinuria and hypertension, and progressive renal failure in most of the patients. Renal histology demonstrates diffuse focal mesangial sclerosis. Because incomplete forms of the syndrome may occur, the nephropathy has become regarded as the common denominator of the syndrome (Habib et al, 1985). Wilms tumor may be diagnosed before, after, or simultaneously with presentation with nephropathy. The majority of the tumors are of favorable triphasic histology (Beckwith and Palmer, 1978). However, there is a high incidence of bilateral Wilms tumor in this syndrome. The genital abnormalities include frank ambiguity, hypospadias, and cryptorchidism. A large number of patients with Denys-Drash syndrome have been noted to have mixed gonadal dysgenesis. These have an increased risk of gonadal tumor of 40% (Table 150-2) (Lee et al, 2006). An interesting and relatively consistent finding with Denys-Drash syndrome is that of calyceal blunting without obstruction (Jadresic et al, 1990). The high mortality rate associated with this syndrome has prompted an aggressive treatment approach with prophylactic bilateral nephrectomy in an attempt to improve the prognosis for these children (Jadresic et al, 1990).

Frasier syndrome, a related disorder caused by mutations in the alternative splice donor site of exon 9 on *WT1*, manifests in similar fashion to Denys-Drash syndrome but with certain important distinctions (Klamt et al, 1998). The nephropathy caused by focal segmental glomerulosclerosis occurs later in life with a more gradual progression to renal failure (Koziell et al, 1999). There is no known predisposition to Wilms tumor. Gonadoblastomas in 46,XY individuals are far more common in Frasier syndrome than in Denys-Drash syndrome, with a gonadal tumor risk of 60% (see Table 150-2). Because 46,XX individuals with Frasier syndrome have normal gonadal development, they would have renal failure. However, it is presumed that many such 46,XX individuals go undiagnosed. Frasier syndrome should be considered in girls with steroid-resistant nephrotic syndrome, primary amenorrhea, and pubertal delay (Gwin et al, 2008).

Figure 150-13. A, Patient with mixed gonadal dysgenesis showing asymmetrical anatomy. B, Hemiuterus and opacified fallopian tube in left inguinal hernia. C, Structures noted in B shown at surgical exploration.

The management of mixed gonadal dysgenesis entails gender assignment, appropriate gonadectomy, and proper screening for Wilms tumor. If the diagnosis is made in the neonatal period, the decision regarding sex of rearing should be based on the potential for normal function of the external genitalia and gonads. Historically, two thirds of patients with mixed gonadal dysgenesis have been raised as female. Potential fertility is not a significant issue in this disorder, and therefore the anatomy of the reproductive tract may direct the decision making. The likelihood of significant androgen imprinting is greater in association with a better-masculinized phenotype, and this may serve as the best clinical guide. For patients with Turner syndrome stigmata and growth below the fifth percentile, growth hormone therapy may be appropriate. If the male gender is elected and the testis can be brought to the scrotum, the decision between careful screening for gonadoblastoma (with physical examination and ultrasonography) versus prophylactic gonadectomy and androgen replacement must be made.

The expanded use of prenatal diagnosis has changed the understanding of 45,X/46,XY mosaicism. Studies have shown that 90% to 95% of all infants with 45,X/46,XY mosaicism have normal-appearing male genitalia (Hsu, 1989). Approximately 25% have abnormal gonadal histology (Chang et al, 1990). Because only a small proportion of those with dysgenetic gonads actually have

ambiguous genitalia, the possibility exists that some males with gonadal dysfunction have 45,X/46,XY mosaicism.

Partial Gonadal Dysgenesis. In 1967, Federman coined the term *dysgenetic male pseudohermaphroditism*, which is a condition closely related to mixed gonadal dysgenesis in that patients with abnormal sex differentiation have two dysgenetic testes rather than one dysgenetic testis and a streak gonad. Others have applied the term *partial gonadal dysgenesis* to this condition, to distinguish it from mixed and complete forms of gonadal dysgenesis. As with mixed gonadal dysgenesis, these individuals typically have a 45,X/46,XY or 46,XY karyotype. They may have a spectrum of external genital abnormalities, depending on the capability of the dysgenetic gonads to produce testosterone. Similarly, persistent müllerian structures are typically present, but to varying degrees depending on MIS secretion by the dysgenetic gonads.

On histology, the dysgenetic testis is found to be composed of immature hypoplastic seminiferous tubules and persistent stroma resembling that seen in the streak gonad.

Patients with partial gonadal dysgenesis are at increased risk for gonadal malignancy. Manuel and colleagues (1976) reported that the incidence of gonadoblastoma or dysgerminoma was 46% by age 40 years. These patients are also at risk for Denys-Drash syndrome (Borer et al, 1995).

The management of partial gonadal dysgenesis, in terms of gender assignment and surveillance for malignancy, is similar to that for patients with mixed gonadal dysgenesis.

46,XY Complete ("Pure") Gonadal Dysgenesis (Swyer Syndrome). Just as 46,XX males were of great importance in discovery

of the TDE, so too have been 46,XY females. **Patients with 46,XY complete gonadal dysgenesis are characterized by normal female genitalia, well-developed müllerian structures, bilateral streak gonads, and a nonmosaic karyotype.** Because there is complete absence of testicular determination in this condition, ambiguity of genitalia is not an issue, but sexual infantilism is the primary clinical problem.

The cause of 46,XY complete gonadal dysgenesis may well be an abnormality of the *SRY* gene that eliminates *SRY* function, or loss of another gene downstream from *SRY* that is necessary for *SRY* protein action. In either case, the absence of testicular determination would permit ovarian differentiation. To date, mutations in the *SRY* gene are the cause of 46,XY complete gonadal dysgenesis in 10% to 15% of cases. Mutation in the desert hedgehog (*DHH*) gene was noted in three of six patients with 46,XY complete gonadal dysgenesis, suggesting that the genetic origin of this entity is heterogeneous and that *DHH* is likely an important gene in gonadal differentiation (Canto et al, 2004). Investigation of a group of individuals with 46,XY complete gonadal dysgenesis has helped to identify a candidate chromosome interval containing the sex reversal gene to 9p24 (McDonald et al, 1997).

The majority of individuals with 46,XY complete gonadal dysgenesis are in their teens at presentation with delayed puberty and amenorrhea. Breast development is usually absent. The serum concentration of gonadotropins is abnormally elevated, which leads the clinician to the determination of karyotype and the subsequent diagnosis (Grumbach and Conte, 1998). The high concentration of serum LH in these patients is thought to be responsible for the increased androgen levels that lead to clitoromegaly in some individuals (Fig. 150-14).

The histology of the streak gonad is similar to that of Turner syndrome, with fibrous connective tissue resembling wavy ovarian stroma but without follicles. Some histologic variability has been noted, with more proliferative-appearing stroma in some and, rarely, preservation of intact primordial follicles. This variability in ovarian histology is thought to support the hypothesis that these

TABLE 150-2 Risk of Germ Cell Malignancy According to Diagnosis

Figure 150-14. A and B, External genitalia of a 15-year-old girl with amenorrhea and hirsutism who was diagnosed with 46,XY gonadal dysgenesis, demonstrating clitoromegaly and urogenital sinus. (Courtesy S. Bauer, MD.)

Figure 150-15. Pathology of gonadoblastoma discovered in the patient shown in Figure 150-14 with 46,XY gonadal dysgenesis. Encapsulated nests of gonadoblastoma consist of small sex cord-type cells arranged around rounded spaces of amorphous eosinophilic material and interspersed germ cells. (Courtesy S. Bauer, MD.)

gonads developed as ovaries in utero (German et al, 1978). This would resemble the process that occurs in the streak gonad of Turner syndrome.

Patients with 46,XY complete or pure gonadal dysgenesis are at significant risk for germ cell tumors. There appears to be up to a 35% risk of tumor development by age 30 years (Manuel et al, 1976; see Table 150-2). Gonadoblastoma is most common, and it is frequently bilateral (Fig. 150-15). Other tumors that may arise in this patient population include embryonal carcinoma, endodermal sinus tumor, choriocarcinoma, and immature teratoma. These more highly malignant tumors occur in fewer than 10% of patients with 46,XY complete gonadal dysgenesis (Scully, 1981).

Management of 46,XY complete gonadal dysgenesis entails removal of both streak gonads and proper cyclic hormone replacement with estrogen and progesterone.

Embryonic Testicular Regression and Bilateral Vanishing Testes Syndromes

The syndromes of embryonic testicular regression and bilateral vanishing testes are characterized by patients with a 46,XY karyotype and absent testes in whom there is clear evidence of testicular function at some point during embryogenesis. The syndrome entails the presence of testes that “vanish” during embryogenesis and is distinguished from pure gonadal dysgenesis, in which there is no evidence of testicular function in utero.

These syndromes have been regarded as synonymous by some authors. Other authors, including Migeon and colleagues (1994), have suggested a rational stratification whereby *embryonic testicular regression* refers to loss of testicular tissue within the first trimester and is associated with ambiguity of external genitalia, whereas

bilateral vanishing testes syndrome refers to individuals in whom male sexual differentiation of ducts and genitalia took place but loss of testicular tissue occurred subsequently in utero.

The cause of these disorders remains unclear. It is possible that regression of the testes in utero is caused by a genetic mutation, a teratogen, or bilateral torsion. A genetic cause is supported by the finding of familial instances of XY gonadism that might be consistent with the rare recessive trait. Marcantonio and associates (1994) suggested the possibility that embryonic testicular regression represents a variant of 46,XY gonadal dysgenesis. They noted a group of patients with absent testes but evidence of incongruity between the extent of Leydig cell and Sertoli cell function, suggesting that gonadal tissue in these patients was intrinsically abnormal before the testicular regression occurred. The occurrence of embryonic testicular regression in several subjects from one family in their series suggested a genetic basis for the condition, and the pattern of inheritance implicated the involvement of an X chromosome gene. In another group of patients, these authors noted multiple congenital anomalies, suggesting either a mutation in a single gene that functions in several developmental pathways or a defect of multiple genes that might be the result of a large chromosomal deletion. A heterozygous mutation in *SF1* has been noted in a series of patients with bilateral vanishing testes syndrome with micropenis (Philibert et al, 2007).

Clinically, these two syndromes represent a spectrum of phenotypes ranging in severity from complete female, to varying degrees of genital ambiguity in the embryonic testicular regression syndrome, to a normal male phenotype with microphallus and empty scrotum in the bilateral vanishing testes syndrome (Edman et al, 1977). The diagnosis can be made on the basis of a 46,XY karyotype, castrate levels of testosterone, elevated serum LH and FSH (Jarow et al, 1986), and undetectable MIS level (Lee et al, 2003). In the most severe form of embryonic testicular regression syndrome, agonadism is discovered in a 46,XY phenotypic female with no internal genital structures. This picture is presumed to result when the testis has elaborated MIS but vanishes at approximately day 60 to 70 of gestation, before the elaboration of androgen. Because of the absence of gonadal androgens later in fetal development and transient expression of MIS, the individual goes on to develop a sexually infantile female phenotype but lacks any internal ductal structures. At an intermediate point in the clinical spectrum is the 46,XY patient with absent gonads and internal ductal structures but with ambiguous genitalia resulting from incomplete elaboration of androgen by the vanishing testes. Finally, in bilateral vanishing testes syndrome, patients may appear as agonadal XY phenotypic males with fully developed wolffian structures but an empty scrotum, absent prostate, and microphallus. This represents testicular loss after complete anatomic development of the male external genitalia within the first trimester.

On surgical exploration of patients with bilateral vanishing testes syndrome, rudimentary cord structures are usually identified and biopsy of their distal ends demonstrates no recognizable testicular tissue histologically (Bergada et al, 1962). Atrophic epididymal remnants are occasionally seen.

The management of patients with embryonic testicular regression syndrome or bilateral vanishing testes syndrome is dictated by their position in the clinical spectrum of either disorder. Sexually infantile phenotypic females require estrogen supplementation at the time of expected puberty for development of secondary sexual characteristics and may require vaginal dilation or vaginoplasty. Similarly, phenotypic males require long-term androgen replacement beginning at the time of expected puberty. A study of 21 males so treated demonstrated that replacement therapy started at the correct time caused a normal pubertal growth spurt with normal secondary sex characteristics including penile growth, together with normal bone maturation (Aynsley-Green et al, 1976). In addition, these patients may benefit from placement of testicular prostheses. Patients with embryonic testicular regression syndrome and ambiguous genitalia require individualized assessment to determine the optimal gender assignment.

(From Diamond D. *Intersex disorders: I and II. AUA Update Series*, vol. IX, lessons 9 and 10. Houston: American Urological Association Office of Education; 1990.)

Ovotesticular Disorder of Sex Development

Ovotesticular DSD describes individuals who have both testicular tissue with well-developed seminiferous tubules and ovarian tissue with primordial follicles, which may take the form of one ovary and one testis or, more commonly, one or two ovotestes.

Both the external genitalia and internal duct structures of ovotesticular DSD display gradations between male and female. In most patients the external genitalia are ambiguous but masculinized to variable degrees, and 75% are raised as male. Among those raised as male, hypospadias and chordee occur in approximately 80%. Among those patients raised as female, two thirds have clitoromegaly. Virtually all patients have a urogenital sinus, and in most patients a uterus is present (Figs. 150-16 and 150-17). The ovary is found in a normal location, more commonly on the left side. The testis or ovotestis may reside at any point along the path of testicular descent. Testes and ovotestes are more commonly located on the right side (Blyth and Duckett, 1991; Mittwoch, 2000). Sixty percent of gonads palpable in the inguinal canal or labioscrotal folds are ovotestes, which may be clinically suspected on the basis of a difference in firmness at either end of the gonad, consistent with polar segregation of ovarian and testicular tissue (Grumbach and Conte, 1998). Detailed evaluation of gonads from a large cohort of patients with ovotesticular DSD from South Africa suggests three distinct patterns of gonad development: admixed (central core containing stroma and a mixture of ovarian and testicular tissue), compartmentalized (ovarian tissue in upper pole with lower pole of testicular tissue encapsulated by mantle of ovarian tissue), and bipolar (strict polar distribution of testicular and ovarian tissue) (Wiersma and Ramdial, 2009).

Approximately 60% of patients with ovotesticular DSD have a 46,XX karyotype; 33% are mosaics with a second cell line containing a Y chromosome (46,XX/46,XY; 46,XX/46,XXY), and 7% are 46,XY. Chimerism (mosaicism) has been thought to result from fusion of a fertilized ovum with its polar body, fusion of two nuclei, or double fertilization. It has also been suggested that ovotesticular DSD may result from hidden mosaicism with a Y cell line. Ortenberg and colleagues (2002) demonstrated the SRY gene in ovotestes of all eight patients with ovotesticular DSD studied, supporting somatic mosaicism. Other studies have demonstrated heterogeneity of Y-specific DNA regions detected in patients with ovotesticular DSD (Hadjithanasiou et al, 1994). This supports a non-Y chromosome-related mechanism responsible for 46,XX ovotesticular DSD, such as mutation in an autosomal or X-linked gene involved in sex determination. Berkovitz and colleagues (1991)

suggested that 46,XY ovotesticular DSD may be a form of partial gonadal dysgenesis. According to this theory, a partial defect in testis determination results in both testicular and ovarian development. This is supported by the finding of ovarian stroma in some dysgenetic testes.

Just as the differentiation of external genitalia is variable in ovotesticular DSD, differentiation of the internal ducts is also quite variable and is related to the function of the ipsilateral gonad. Fallopian tubes are consistently present on the side of the ovary, and a vas deferens is always present adjacent to a testis (Berkovitz et al, 1991). The ovotestis, which comprises two thirds of gonads in ovotesticular DSD, is associated with a fallopian tube in two thirds of patients and with either a vas deferens only or both structures in one third of patients.

The ovarian portion of the ovotestis is frequently normal, whereas the testicular portion is typically dysgenetic. Therefore, although ovulation and pregnancy have been reported for female patients with 46,XX ovotesticular DSD, male fertility has not been clearly documented.

The incidence of gonadal tumors is approximately 3% in 46,XY ovotesticular DSD and rare in 46,XX ovotesticular DSD. Both gonadoblastoma and dysgerminoma have been described (Verp and Simpson, 1987).

The most important aspect of management in ovotesticular DSD is gender assignment. Sex assignment should be based on the functional potential of external genitalia, internal ducts, and gonads, according to the findings at laparoscopy or laparotomy. Unlike patients with most other forms of gonadal dysgenesis, individuals with ovotesticular DSD have the potential for fertility if raised as female with the appropriate ductal structures. Pregnancies have been reported in patients with ovotesticular DSD, the majority with the 46,XX karyotype (Starceski et al, 1988). If the patient is to be raised as female, all testicular and wolffian tissue should be removed. For those patients with an ovary, this is straightforward; if an ovotestis is present, surgical cleavage of the gonad with excision of the testicular portion has been performed successfully by Nihoul-Fekete and colleagues (1984). They recommend postoperative stimulation with hCG to confirm that all testicular tissue has been removed. In some settings the cleavage plane between testicular and ovarian tissues is unclear, as in admixed pathology as described earlier; gonadectomy is advisable. When ovarian tissue is preserved, normal ovarian function can occur at puberty, although hormonal replacement may be necessary. Careful surveillance for potential gonadal tumors in the patient raised as female is also advisable. If a male gender is assigned, as has been

most common historically, all ovarian and müllerian tissue should be removed. Consideration should be given to gonadectomy at puberty with appropriate androgen replacement in this setting, given the high risk of malignancy and unlikelihood of male fertility. At the very least, long-term gonadal surveillance ultrasound for tumor development would seem appropriate.

46,XX Disorder of Sex Development (Masculinized Female)

46,XX DSD (masculinized female) is a disorder of phenotypic sexual development in which 46,XX individuals with ovaries have a partially masculinized phenotype and ambiguous genitalia. By far the most common cause of the masculinized female is CAH, which is the most common cause of ambiguous genitalia in the newborn. Two very rare causes of 46,XX DSD (masculinized female) are maternal ingestion of androgens and virilizing tumors in the mother.

Congenital Adrenal Hyperplasia. The adrenogenital syndrome caused by CAH is a classic example of an inborn error of metabolism—in this case, an error involving cortisol synthesis. A defect in any one of the five enzymes involved in the cortisol biosynthetic pathway (cholesterol side chain cleavage enzyme, 3 β -hydroxysteroid dehydrogenase, 17-hydroxylase, 21-hydroxylase, and 11-hydroxylase) may result in CAH. The most commonly recognized syndromes result from a deficiency of one of the terminal two enzymes of glucocorticoid synthesis (21-hydroxylase or 11-hydroxylase) (New and Levine, 1984) (Fig. 150-18). As a result of deficiency of either terminal enzyme, formation of hydrocortisone is impaired, causing a compensatory increase in the secretion of adrenocorticotropic hormone (ACTH). This increase enhances formation of adrenal steroids proximal to the enzymatic defect and a secondary increase in the formation of testosterone, the active androgen in CAH.

KEY POINT: CONGENITAL ADRENAL HYPERPLASIA

- The most commonly recognized syndromes of CAH result from a deficiency of one of the terminal two enzymes of glucocorticoid synthesis (21-hydroxylase or 11-hydroxylase).

A deficiency of steroid 21-hydroxylase is responsible for 95% of cases of CAH; it occurs with an incidence ranging from 1 in 5000 to 1 in 15,000 in the United States and Europe. The highest incidence, 1 in 490, is reported in the Yupik Alaskan Eskimo population (New et al, 1994). Clinically, patients are divided into three categories: (1) salt wasters (patients with virilization and aldosterone deficiency), (2) simple virilizers (patients with virilization, but without salt wasting), and (3) nonclassic patients (those without evidence of virilization or salt wasting). Dramatic progress has been made in understanding the molecular basis of CAH, and 95% of the mutations that account for CAH have been identified. The wide clinical spectrum of the disease appears to represent different degrees of enzymatic compromise conferred by specific, identifiable genetic defects.

The 21-hydroxylase gene (*CYP21A2*) is located on chromosome 6p21.3 within the major human leukocyte antigen (HLA) complex and is transmitted in an autosomal recessive pattern (Wilson et al, 1995). Adjacent to the *CYP21A2* gene, separated by 30 kb, and adjacent to and alternating with *C4B* and *C4A* genes encoding the fourth component of serum complement is the *CYP21* pseudogene (*CYP21PA1*), so called because it encodes no proteins and is therefore inactive (Tusie-Luna and White, 1995). The inactive *CYP21PA1* is 98% homologous to the active gene *CYP21A2*. During meiosis, a gene conversion may occur that transfers segments from the *CYP21PA1* gene to the *CYP21A2* gene, rendering it inactive. Thus far, all mutations causing 21-hydroxylase deficiency appear to result from either a complete deletion of the genes *C4B* and *CYP21B* (a product of misalignment and unequal crossing-over between chromatids during meiosis). To date approximately 15 mutations constitute 90% to 95% of alleles and are derived from intergenic recombination of DNA sequences between the *CYP21A2* gene and the highly homologous *CYP21PA1*, whereas the remaining are spontaneous mutations (Forest, 2004). Approximately 100 different *CYP21* mutations have been reported.

The majority of patients with CAH secondary to 21-hydroxylase deficiency exhibit one of the two classic forms of the disease: 75% have salt wasting and 25% have simple virilization (Kohn et al, 1995). The higher proportion of patients with the salt-wasting form of the disease recognized in more recent series has been attributed to improved diagnostic capabilities and a high level of clinical suspicion as well as to increased survival as a result of prenatal screening and proper mineralocorticoid supplementation (Fife and Rappaport, 1983). Neonatal screening programs for CAH have been

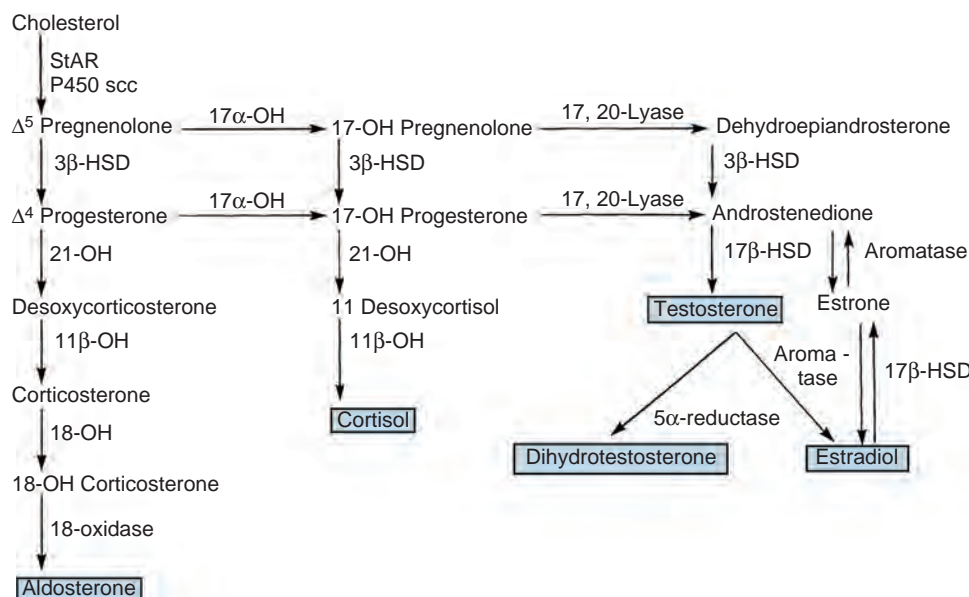

Figure 150-18. Steroid biosynthetic pathway for mineralocorticoid, glucocorticoid, and sex steroid hormone production.

credited with increasing the rate and shortening the time to diagnosis, particularly in males with the salt-wasting form of the disease. This has also proven to be an important means of diagnosing the simple virilizing form in the male and the nonclassic forms in some males and females (Brosnan et al, 1999).

In the female with the classic salt-wasting and simple virilizing forms of the disorder, a masculinized female results. Because impaired steroidogenesis begins early in life—at the time of formation of the external genitalia (beginning at 10 weeks' gestation)—there is virtually always evidence of some degree of masculinization at birth. This manifests as enlargement of the clitoris and varying degrees of labial fusion (Fig. 150-19). In addition, the vagina and urethra open into a common urogenital sinus. The enlargement of the clitoris may be so dramatic as to make it appear to be a hypospadiac penis with bilateral cryptorchidism or, rarely, a fully masculinized urethra to the tip of an apparent glans penis (Fig. 150-20). The severity of the virilization is usually greater in infants who experience salt wasting but not uniformly so. Prader (1958) classified the degrees of virilization of external genitalia in females with CAH (Fig. 150-21). The müllerian structures in these patients are typically normal. A recent study suggests an increased incidence (Nabhan and Eugster, 2007) of upper tract abnormalities (hydronephrosis, duplication) in CAH.

In both males and females with the salt-losing variant of CAH, symptoms begin within the first few weeks after birth, with failure to regain birth weight, progressive weight loss, and dehydration. In severely affected infants, adrenal crises occur within

the first 10 to 21 days of life (Grumbach and Conte, 1998). Vomiting is prominent and can be so extreme that a mistaken diagnosis of pyloric stenosis is made, particularly in the male. Without therapy, death may rapidly ensue from hyperkalemia, dehydration, and shock. In the male infant, in particular, the classic fluid and electrolyte abnormalities of CAH may be mimicked by urosepsis secondary to reflux or obstructive uropathy, which should be ruled out (Mastrandrea et al, 2005). After birth there is progression of masculinization of the untreated female; pubic and axillary hair develop prematurely, acne appears, and the voice deepens. There is rapid somatic maturation, resulting in premature epiphyseal closure and short adult stature. Although the internal genitalia are female, breast development and menstruation do not occur unless the excessive androgen production is suppressed by adequate steroid therapy.

In the male without salt wasting the chief clinical manifestations are those of isosexual precocity. The infant appears normal at birth, but signs of sexual and somatic precocity appear within the first 2 to 3 years of life. Although the testes remain normal in size, enlargement of the penis, scrotum, and prostate occur, accompanied by the appearance of pubic hair, acne, and deepening of the voice. The musculature is well developed (prompting the descriptive term "little Hercules"), and bone age is more advanced than appropriate for the chronologic age. The syndrome often goes unrecognized in the non-salt-wasting male until signs of androgen excess, such as accelerated height and precocious pubic hair, appear later in childhood.

Classification by Prader of the various degrees of masculinization of the external genitalia in females with congenital adrenal hyperplasia, which has been applied by some authors to intersex states in general. (From Prader A. Die Häufigkeit der kongenitalen androgenitalen Syndroms. *Helv Paediatr Acta* 1958;13:426.)

In the non-salt-wasting male, two major long-term implications are short stature as well as infertility in 20% to 40%. Premature epiphyseal closure will result unless early medical control is instituted. This emphasizes the value of neonatal screening. Infertility has been noted in 30% of CAH males, often related to the finding of adrenal rest nodules most reliably diagnosed with scrotal ultrasonography. These nodules, present in 25% to 30% of males with CAH, represent hypertrophy of adrenal rests as a result of ACTH stimulation and when associated with impaired fertility warrant periodic scrotal ultrasonography, intensified glucocorticoid suppression, and possibly testis-sparing excision (Claahsen-van der Grinten et al, 2008). Some advocate sperm cryopreservation in postpubertal males with adrenal rest tumors. In addition, poor control of the disease in boys with classic CAH has been associated with small testes and infertility with reduced sperm counts (New and Wilson, 1999). This is a result of peripheral aromatization of excess androgen to estrogen that suppresses pituitary gonadotropins.

In classic 21-hydroxylase deficiency, plasma levels of progesterone and 17-hydroxyprogesterone are markedly elevated. Urinary levels of 17-ketosteroids and pregnanetriol are elevated. The diagnosis may be made biochemically with the use of radioimmunoassay of plasma 17-hydroxyprogesterone, which has replaced the more cumbersome 24-hour urine collection of metabolites (e.g., pregnanetriol). A pelvic ultrasound study demonstrating the presence of müllerian tissues is confirmatory. Some investigators have suggested that the finding of abnormally enlarged or "cerebriform"-appearing adrenal glands on neonatal ultrasonography, available before biochemical results, may represent the earliest diagnostic tool for CAH (Hernanz-Schulman et al, 2002).

More aggressive screening for 21-hydroxylase deficiency has provided considerable benefits. In one series, despite sexual ambiguity, one third to one half of the affected female newborns were not diagnosed as having 21-hydroxylase deficiency until they were identified by the screening test (Pang et al, 1985).

Nonclassic 21-hydroxylase deficiency represents an attenuated, late-onset form that is variable in its clinical severity because of partial deficiency of 21-hydroxylase and timing of onset. These patients do not have cortisol deficiency but do have hyperandrogenism. New and Wilson (1999) found the nonclassic 21-hydroxylase deficiency to be the most common autosomal recessive disorder in humans, with an incidence of 1 in 100. The presenting symptoms in females are commonly hirsutism and oligomenorrhea, male pattern baldness, and polycystic ovaries. In a recent study, 32% of women with nonclassic 21-hydroxylase deficiency were diagnosed only after delivering an offspring diagnosed with 21-hydroxylase deficiency CAH. In men with the nonclassic form of 21-hydroxylase deficiency, oligospermia and subfertility have been presenting features, and reversal of infertility with glucocorticoid therapy has been reported. Typically, lower doses of glucocorticoid are required for management of the nonclassic form of CAH.

A deficiency of 11 β -hydroxylase accounts for roughly 5% of cases of CAH. Both classic and mild forms have been recognized. Unlike 21-hydroxylase, 11 β -hydroxylase is not HLA linked. The defect results from mutations in the *CYP11B1* gene located on the long arm of chromosome 8 (Merke et al, 1998). To date, more than 50 mutations have been described that result in enzyme inactivation (Nimkarn and New, 2008). Like 21-hydroxylase deficiency, the nonclassic variant of 11 β -hydroxylase deficiency (late onset) is characterized by signs and symptoms of androgen excess in childhood or adolescence. Hypertension is a common finding in patients with this type of CAH, and it is believed to be secondary to increased serum levels of deoxycorticosterone (DOC). Although most of the patients are hypertensive, some are normotensive and others experience only intermittent hypertension. Marked virilization occurs in the severe form of the defect and may be as severe as in those patients with a 21-hydroxylase deficiency. In the late-onset form, mild virilization occurs in prepubertal and postpubertal patients.

The diagnosis of 11 β -hydroxylase deficiency can be confirmed by finding increased plasma levels of 11-deoxycortisol and 11-DOC. Urinary levels of 17-ketosteroids and 17-hydroxycorticoids

are increased. The treatment with glucocorticoids is identical to that of patients with 21-hydroxylase deficiency.

The least common enzyme deficiency responsible for a virilizing form of CAH is 3 β -hydroxysteroid dehydrogenase. This deficiency affects the early steps in steroid biosynthesis in both adrenals and gonads, resulting in inability to convert 3 β -hydroxysteroids to 3-ketosteroids. As a result, the severe form leads to impaired synthesis of aldosterone, cortisol, and sex steroids. Affected females exhibit mild clitoromegaly and labial fusion accompanied by symptoms of aldosterone and cortisol deficiency.

Two homologous genes have been identified for 3 β -hydroxysteroid dehydrogenase, both of which contain four exons (Merke et al, 1998). A number of mutations giving rise to the syndrome have been described. This defect has an autosomal recessive inheritance pattern and is heterogeneous in its biochemical and clinical appearance. A non-salt-losing form and mild- and late-onset forms have been described, although the nonclassic form appears to be exceedingly rare.

The diagnosis of 3 β -hydroxysteroid dehydrogenase is based on finding increased serum levels of 17-hydroxypregnenolone and dehydroepiandrosterone (DHEA). Pelvic ultrasound evaluation confirming the presence of müllerian tissue would be supportive. Treatment is similar to that of patients with 21-hydroxylase deficiency.

Currently, one of the most exciting aspects of CAH is the capability of diagnosing and treating the disorder prenatally. Prenatal diagnosis of CAH in the at-risk fetus was initially made by a measurement of amniotic fluid for 17-hydroxyprogesterone at 16 to 17 weeks' gestation (Laue and Rennert, 1995). Currently the diagnosis is made during the first trimester by HLA genotyping or by DNA analysis of genes within the HLA complex in cells obtained by chorionic villus sampling at 9 to 11 weeks' gestation (Hughes, 2002). Treatment of the mother with dexamethasone, which crosses the placenta, suppresses fetal secretion of ACTH, thereby preventing virilization of the genitalia. However, treatment should be instituted as soon as pregnancy is confirmed, and no later than 9 weeks after the last menstrual period, before initial development of the external genitalia (Nimkarn and New, 2007). There are certain complexities to this form of management. The diagnosis of CAH in the fetus may be determined on chorionic villous cells or on cells from amniotic fluid for families in which a prior member was affected. Therefore, it is not possible to confirm the diagnosis before therapy is initiated. Because virilization is not a concern with the male fetus and three of four female fetuses at risk are unaffected, given the autosomal recessive pattern of inheritance, seven of eight fetuses may be treated unnecessarily. Therefore, one goal in therapy has been earlier diagnosis to avoid unnecessary treatment. A promising approach that may enhance the prenatal diagnosis of CAH as early as 9 weeks' gestation is PCR analysis of free fetal DNA, from circulating trophoblastic cells, in the maternal circulation, which allows detection of Y chromosome, thus avoiding treatment of males (Rijnders et al, 2001).

A number of series have established the effectiveness of prenatal treatment for CAH with dexamethasone in 85% of cases (Migeon, 1990; Pang et al, 1990; Speiser et al, 1990). In some neonates there is no evidence of masculinization, suggesting totally successful therapy. In another group there is milder masculinization than that noted in an affected sibling. Although compliance and timing of initiation of treatment have been variable from series to series, this heterogeneity of response to therapy raises intriguing questions about the mechanisms involved in virilization of the CAH fetus. In addition, prenatal treatment with dexamethasone has raised ethical concerns. Although there is no arguing its ability to prevent androgen effects on the genitalia and potentially the brain of affected females, the long-term effects of dexamethasone on unaffected fetuses undergoing treatment prenatally remain largely unknown. A study by Meyer-Bahlburg and colleagues (2004a) demonstrated no cognitive or developmental motor impairment to have resulted from prenatal treatment of CAH fetuses, but others have suggested potential deleterious effects on verbal working memory (Hirvikoski et al, 2007). Miller (1999) and

others have advocated the use of prenatal treatment for CAH only as an experimental therapy in large centers and under institutional review board scrutiny. The importance of long-term follow-up of these neonates has been emphasized (Speiser, 1999).

Hughes (2002) and others have emphasized the close correlation in CAH of genotype and phenotype. New and colleagues (2013) noted a genotype-phenotype correlation in 21 of 45 cases. Certain genotypes were more frequent in specific ethnic groups. This has a number of practical implications. Molecular biologists can now predict not only the risk of a couple having an affected child but also the likely clinical form of the disease. Therefore, genotypes of severe mutations would motivate prenatal treatment, whereas genotypes of less severe mutations would not. In addition, less severe genotypes in the newborn would allow for modification of corticosteroid treatment to minimize side effects.

The treatment of affected children with hydrocortisone in childhood and adolescence achieves a number of goals, as noted by Bongiovanni and Root (1963): "to supply the deficient hormone; to suppress pituitary ACTH secretion and hence adrenal androgens and clinical virilization; to forestall abnormally rapid somatic growth and osseous advance; to permit normal gonadal development; and to correct salt-water loss or hypertension in the complicated forms." The required dose of glucocorticoid may be predicted by genotype, as noted by Hughes (2002), but should be adjusted for the individual patient based on bone age, linear growth, 24-hour excretion of ketosteroids, and clinical evidence of glucocorticoid deficiency or excess (Grumbach and Conte, 1998). The effectiveness of therapy may be assessed by measuring morning plasma 17-hydroxyprogesterone levels. Those children with the salt-losing form of the disease require increased salt intake and mineralocorticoid treatment in addition to hydrocortisone therapy. After control of electrolytes and blood pressure has been achieved in the acute setting, maintenance therapy with fludrocortisone should be instituted (Laue and Rennert, 1995; Grumbach and Conte, 1998). The preferred cortisol replacement is oral hydrocortisone (10 to 20 mg/m² per day in three divided doses). Doubling or tripling the oral dose of hydrocortisone is often recommended during physically stressful events such as surgery or infection. Infants with the salt-wasting form of CAH require replacement with fludrocortisone (0.1 to 0.2 mg/day) (Antal and Zhou, 2009).

In significantly virilized females (who will not have been diagnosed and treated prenatally), it is appropriate to perform feminizing genitoplasty at 3 to 6 months of age, when a well-established course of medical therapy has been instituted, the risks of anesthesia have become minimal, and the child has grown large enough to make the procedure technically feasible (Passerini-Glazel, 1990). **Long-term fertility in males and feminization, menstruation, and fertility in females can be anticipated in the well-treated patient.** Indeed, this potential in even the most masculinized female CAH patient has provided support for feminizing genitoplasty in virtually all 46,XX CAH patients. Although female gender rearing is supported by the 2006 consensus statement, it has been recently challenged by Lee and Husmann for those patients with 46,XX CAH who appear unambiguously male, for whom they recommend consideration of male gender assignment (Lee et al, 2010).

An important area of recent research has been the potential imprinting of the brain by elevated prenatal androgen levels. A number of recent studies confirm that prenatal hyperandrogenization is associated with masculinization of gender-related behavior but not masculinization of gender identity. Meyer-Bahlburg and associates (Meyer-Bahlburg et al, 2004b, 2008; Dessens et al, 2005) noted a close correlation between hormonal abnormalities as a function of severity of enzyme deficiency with sexual orientation (homosexuality, bisexuality rates). Furthermore, Berenbaum and colleagues (2003, 2004) noted that in females with CAH and virilized genitalia, psychological development is not compromised in those who are reared as females and receive good medical care. Meyer-Bahlburg and associates (2004a) noted in 46,XX CAH girls that marked masculinization of gender-related behavior in prenatally hyperandrogenized CAH girls was not associated with masculinization of gender identity. Therefore the psychosexual evidence

to date supports maintaining female gender in masculinized CAH patients diagnosed in infancy. Indeed, proper psychological support should be a component of long-term follow-up.

In an interesting new finding, both male and female patients with classic CAH have been noted on magnetic resonance imaging to have smaller amygdala volumes than controls, and altered amygdala function. The amygdala, regulated by glucocorticoids, is important in processing emotion (Ernst et al, 2007).

An intriguing area of surgical innovation in the management of CAH has been the experimental use of "prophylactic" adrenalectomy for selected patients. This approach is based on the premise that in certain patients it is more difficult to maintain adrenal suppression than to prevent adrenal crises. Clinically, these patients are the salt losers and extremely virilized females. For those with this most severe form of 21-hydroxylase deficiency, adequate suppression of adrenal production has required significant degrees of hypercortisolism, associated with poor growth, obesity, and infertility (in 40%). For the 25% of CAH patients who completely lack 21-hydroxylase enzyme activity and therefore produce neither cortisol nor aldosterone, adrenalectomy may be a practical approach (VanWyk et al, 1996). In general, these patients may be identified genotypically as homozygotes or compound heterozygotes for "null alleles" of the CYP21 gene (VanWyk et al, 1996). In a series of 18 patients with long-term follow-up, VanWyk and Ritzen (2003) noted bilateral adrenalectomy to be safe and effective in managing severe forms of CAH in which patients repeatedly escaped adrenal suppression. Most of these patients reported a better quality of life after bilateral adrenalectomy. In a recent series bilateral adrenalectomy proved more successful for those patients pursuing fertility rather than control of obesity and hyperandrogenism (Ogilvie et al, 2006).

Although these patients are rendered addisonian by this surgery, those with the most severe form of CAH would have a poor intrinsic adrenal response to metabolic stress (Gunther et al, 1997). One theoretic disadvantage of this approach is that if gene therapy were to one day allow functional CYP21 genes to be introduced into adrenal cortical tissue, adrenalectomized patients would not be candidates for such therapy (VanWyk et al, 1996).

Males with CAH must be followed for testicular adrenal rest tumors as a potential cause of infertility. This is ideally performed with annual screening testicular ultrasonography (Kang et al, 2011). **46,XX Disorder of Sex Development (Masculinized Female) Secondary to Maternal Androgens and Progestins and Maternal Tumors.** The masculinization of a female fetus as a result of maternal administration of synthetic progestational agents or androgens is a rare occurrence; lessons have been learned from prior unfortunate experiences. Historically, progestational agents were used to prevent threatened abortion. In one large series, masculinization occurred in 2% of female infants whose mothers were treated with progestins during pregnancy (Ishizura et al, 1962). In addition, danazol, a testosterone derivative used to treat endometriosis, has been associated with virilization of the female fetus. The degree to which any androgen or progestational agent affects female fetal development is a function of the strength of the agent, its maternal dosage, and timing and duration of administration (Bongiovanni and McFadden, 1960).

Very rarely, a maternal ovarian or adrenal tumor has virilizing effects on a female fetus. More typically, such a tumor has virilizing effects on the mother but no apparent effect on the fetus. Ovarian tumors that have resulted in masculinization of the female fetus include arrhenoblastoma, hilar cell tumor, lipoid cell tumor, ovarian stromal cell tumor, luteoma of pregnancy, and Krukenberg tumor (Calaf et al, 1994).

Rarer still are maternal adrenal tumors (adrenocortical carcinoma and adenoma), which have masculinizing effects on the female fetus.

Aromatase deficiency represents an even rarer cause of transplacental transport of excess androgens to the fetus. The cytochrome P450 aromatase enzyme catalyzes the conversion of androgens to estrogens. Normally, weak androgens produced by the fetal adrenal gland are converted to estrogens by placental aromatase and pass

to the maternal circulation. Mutations of the *CYP19* aromatase gene can result in profound virilization of the female fetus and mother during pregnancy. Although maternal virilization resolves postnatally, it recurs in subsequent pregnancies.

In any case of exogenous androgen effect on a female fetus, normal endocrine status is recognized postnatally and management is confined to external genital reconstruction, as required.

46,XY Disorder of Sex Development (Undermasculinized Male)

The term *46,XY DSD (undermasculinized male)* refers to 46,XY individuals with differentiated testes who exhibit varying degrees of feminization phenotypically. Impaired male differentiation in these patients is secondary to inadequate secretion of testosterone by the testes at the necessary period in development, inability of target tissue to respond to androgen appropriately, or impaired production or action of MIS.

Leydig Cell Aplasia (Luteinizing Hormone Receptor Abnormality). Leydig cell aplasia as a cause of undermasculinization of the male was first reported by Berthezene and colleagues in 1976. In its pure form, this rare disorder is characterized by a normal 46,XY male karyotype associated with a normal-appearing female phenotype. Typically, testes are palpable in the inguinal canals or labia majora. On investigation, there are no müllerian structures and the vagina is short. A low testosterone level is noted in conjunction with an elevated LH concentration. The absence of a rise in serum testosterone level after hCG stimulation is characteristic of this disorder (Brown et al, 1978). Physiologically, this disorder represents a spectrum between absent Leydig cells and Leydig cells with abnormal LH receptor (David et al, 1984). Because a number of inactivating mutations have been found in the LH receptor gene, a correlation can be made between the phenotype of patients with Leydig cell hypoplasia and the activity of their LH receptor alleles (Richter-Unruh et al, 2004). It is transmitted as an autosomal recessive trait expressed only in males. Incomplete forms of the syndrome occur, with the mildest form being expressed as primary hypogonadism with normal male external genitalia (Lee et al, 1982).

The clinical diagnosis of Leydig cell aplasia, or LH receptor abnormality, is typically made as a result of sexual infantilism and the absence of development of secondary sexual characteristics or the discovery of palpable gonads in the inguinal canal or labia on physical examination (Arnholt et al, 1985). The differential diagnosis includes androgen insensitivity syndrome or a terminal defect in androgen synthesis. The histology of the abnormal testes demonstrates absence of Leydig cells in intratubular spaces with normal Sertoli cells.

Disorders of Testosterone Biosynthesis

A defect in any of the five enzymes required for the conversion of cholesterol to testosterone can cause incomplete (or absent) virilization of the male fetus during embryogenesis. The first three enzymes (cholesterol side chain cleavage, 3 β -hydroxysteroid dehydrogenase, and 17 β -hydroxylase) are present in both adrenals and testes. Therefore, their deficiency results in impaired synthesis of glucocorticoids and mineralocorticoids in addition to testosterone. For all five enzyme deficiencies, the pattern of inheritance is autosomal recessive.

StAR (Cholesterol Side Chain Cleavage Enzyme) Deficiency. The first step in gonadal and adrenal steroidogenesis is conversion of cholesterol to pregnenolone, which is mediated by a single cholesterol side chain cleavage enzyme known as 450SCC (previously known as 20,22-desmolase). A defect in this enzyme, first described by Prader and Gurtner in 1955, was believed to result in the rare condition congenital lipoid adrenal hyperplasia, so named because the adrenal glands became large and lipid laden. However, more recent evidence suggests that a defect in cholesterol transport rather than a defective enzyme is etiologically responsible (Saenger, 1997). The steroidogenic acute regulatory protein (StAR)

stimulates cholesterol transport from the outer to the inner mitochondrial membrane (site of the cholesterol side chain cleavage complex). This appears to be the rate-limiting step in acute steroid synthesis.

StAR mutations are found in various ethnic groups but are most commonly reported in patients of Japanese, Korean, and Palestinian origin (Bhangoo et al, 2005). Affected 46,XY individuals have female or ambiguous external genitalia with a blind-ending vaginal pouch; intra-abdominal, inguinal, or labial testes; and absence of müllerian structures, consistent with functioning Sertoli cells (Hauffa et al, 1985). Wolffian ducts are present but rudimentary. Infants often are seen in the first few weeks of life with severe adrenal insufficiency and salt wasting, but delayed presentation has been reported (Lekarev et al, 2012).

A diagnosis of StAR (cholesterol side chain cleavage enzyme) deficiency should be entertained in any neonate with nonvirilized female external genitalia and evidence of cortisol and aldosterone deficiency with hyponatremia, hyperkalemia, and metabolic acidosis. Abdominal computed tomography demonstrates large, lipid-laden adrenal glands.

Management is similar to that for 21-hydroxylase deficiency. Classically, 46,XY patients with this disorder have been raised as females and have undergone gonadectomy (Laue and Rennart, 1995). Because testosterone production was never significant, brain imprinting is not a factor in gender assignment. However, phenotype can be quite variable, such that partial virilization or even normal male genitalia may result (Lekarev et al, 2012).

Cytochrome P450 Oxidoreductase Deficiency. Cytochrome P450 oxidoreductase (POR) deficiency has been recently added to the causes of both 46,XY and 46,XX DSDs. POR is a cofactor to all microsomal P450 enzymes, including 17-hydroxylase, 17,20-lyase, 21-hydroxylase, and aromatase. The condition emerged as a distinct entity through the realization that apparent combined deficiency of 17-hydroxylase and 21-hydroxylase enzymes is a single disorder resulting from lack of POR, a membrane-bound flavoprotein that plays a central role in electron transfer from nicotinamide adenine dinucleotide phosphate (NADPH) to P450 enzymes. It was originally characterized in patients with Antley-Bixler syndrome (a skeletal dysplasia syndrome), some of whom had ambiguous genitalia and abnormal steroidogenesis. Subsequently, it has become clear that POR deficiency can cause DSD unassociated with skeletal dysplasia and characteristics of Antley-Bixler syndrome (Hughes, 2008).

3 β -Hydroxysteroid Dehydrogenase Deficiency. 3 β -Hydroxysteroid dehydrogenase catalyzes the 3 β -hydroxysteroids (pregnenolone, 17-hydroxypregnenolone, and DHEA) to the three ketosteroids progesterone, 17-hydroxyprogesterone, and androstenedione. A congenital deficiency of 3 β -hydroxysteroid dehydrogenase was first described by Bongiovanni in 1962.

Affected individuals have various degrees of incomplete masculinization, resulting from a block in testosterone biosynthesis, and salt-wasting adrenal insufficiency resulting from impaired synthesis of aldosterone and cortisol. The lack of salt-retaining hormone and cortisol results in a salt-losing crisis soon after birth. However, partial deficiencies associated with severe salt wasting occur, consistent with genetic heterogeneity. Two isoenzymes, type I and type II 3 β -hydroxysteroid dehydrogenase, are involved in steroid biosynthesis. These enzymes are encoded by two genes, *HSD3B1* and *HSD3B2*, localized to chromosome 1 at locus p11-p13 (Chang et al, 1993). Classic 3 β -hydroxysteroid dehydrogenase deficiency results from inactivating mutations, 37 of which have been identified, in the *HSD3B2* gene (Welzel et al, 2008).

Males with this deficiency usually exhibit incomplete virilization of the external genitalia, with a small phallus, hypospadias with labioscrotal fusion, a urogenital sinus, and a blind-ending vaginal pouch. Testes are often scrotal, and wolffian ducts develop normally. As with other defects in testosterone biosynthesis, in which normal Sertoli cell function is preserved, müllerian structures are absent.

The diagnosis should be considered in 46,XY males with ambiguous genitalia and signs of adrenal insufficiency. Endocrine study

demonstrating increased levels of 3β -hydroxysteroids confirms the diagnosis.

Management of 3β -hydroxysteroid dehydrogenase is similar to that for patients with 21-hydroxylase deficiency.

17 α -Hydroxylase Deficiency. 17 α -Hydroxylase catalyzes the conversion of pregnenolone and progesterone to 17 α -hydroxypregnenolone and 17-hydroxyprogesterone, respectively, in adrenal and gonadal steroidogenesis. The first case of male pseudohermaphroditism caused by this enzyme deficiency was reported by New in 1970. The gene for this enzyme has been localized to chromosome 10 (Laue and Rennart, 1995).

Affected 46,XY individuals usually have female external genitalia with absent to slight masculinization. A deficiency in 17 α -hydroxylase activity impairs cortisol production, causing ACTH hypersecretion and resulting in increased levels of DOC, corticosterone, and 18-hydroxycorticosterone in the adrenals. These compounds with mineralocorticoid activity produce excess salt and water retention, hypertension, and hypokalemia.

The phenotype of affected individuals varies from female with external genitalia with a blind-ending vaginal pouch to male with perineal hypospadias and chordee. The diagnosis should be considered in a undervirilized male with hypertension. Endocrine laboratory evaluation demonstrates elevated serum progesterone, DOC, corticosterone, 18-hydroxycorticosterone, and ACTH.

Therapy with glucocorticoid replacement brings blood pressure and hypokalemia back to normal by suppressing ACTH and hence adrenal cortical stimulation. Some patients have been raised as females with gonadectomy and estrogen replacement at puberty. In partial forms, typically with reasonable phallic size, patients may be raised as male with testosterone replacement at puberty. Fertility has not been reported in patients with testosterone biosynthetic defects, and inadequate testosterone production makes androgen imprinting a less significant issue for these patients. Therefore, the phenotype may dictate gender assignment.

17,20-Lyase Deficiency. The enzyme 17,20-lyase has been demonstrated to be related to 17 α -hydroxylase in that the activities of both are linked to the same gene product on chromosome 10 (Laue and Rennart, 1995). However, in some patients with the genetic defect both biologic activities are absent, but in others only the 17,20-lyase function appears deficient. Zachmann and colleagues first described this clinical entity in 1972.

In cases in which the deficiency primarily involves 17,20-lyase, cortisol and ACTH secretion are normal. Aldosterone is secreted normally, and hypertension does not result. However, impaired biosynthesis of testosterone in the 46,XY individual results typically in ambiguous rather than totally female genitalia at birth. The deficient masculinization of the external genitalia can range from severe, resulting in a female gender assignment in the neonate, to mild, resulting only in hypospadias. At puberty, the secretion of testicular androgen remains low. Zachmann and colleagues (1982) have postulated that there are two types of 17,20-lyase deficiency—one that is partial and another that is a complete defect.

The diagnosis may be suspected in undervirilized males with absent müllerian derivatives and no defect in glucocorticoid or mineralocorticoid synthesis. At the time of expected pubertal development, the patients may have failure to develop secondary sexual characteristics and elevated gonadotropin levels. The diagnosis may be made prepubertally using hCG and ACTH stimulation.

Management entails plastic reconstruction of the external genitalia and appropriate sex steroid replacement at puberty.

17 β -Hydroxysteroid Oxidoreductase Deficiency. This last enzyme in the testosterone biosynthetic pathway catalyzes the conversion of androstenedione to testosterone, DHEA to androstanediol, and estrone to estradiol. Male undervirilization resulting from a deficiency in 17 β -hydroxysteroid oxidoreductase was first described by Saez and associates in 1971.

Clinically, this is the most interesting enzymatic defect in testosterone biosynthesis in its similarities to 5 α -reductase deficiency. At birth, affected individuals appear to have a normal female phenotype, without significant evidence of virilization.

Therefore a female gender assignment is usually made. However, these individuals have well-differentiated testes located intra-abdominally, inguinally, or in the labia and no müllerian structures. Surprisingly, wolffian ducts are normally developed, which may be secondary to the action of androstenedione or minimal amounts of testosterone produced during embryogenesis (Boehmer et al, 2001). At puberty, there is phallic growth and progressive development of male secondary sexual characteristics. These include increased muscle mass and development of pubic, axillary, and facial and body hair with male distribution. Gynecomastia may occur, and the testes may become palpable (Saez et al, 1972). In some cases, gender reassignment to male has been reported (Imperato-McGinley et al, 1979a; Rosler and Kohn, 1983).

The late onset of virilization is related to the pubertal increase in gonadotropin production, which may partially overcome the block in testosterone biosynthesis.

There is a characteristic hormonal profile in this disorder. In the prepubertal patient, plasma androstenedione and estrone levels may not be increased. At puberty, androstenedione, the immediate precursor of testosterone, is increased to 10 to 15 times the normal plasma concentration (Virdis and Saenger, 1984). Earlier precursors are within normal levels. Plasma testosterone is in the low-normal range. Serum levels of LH and FSH are markedly elevated, typically four to six times normal.

As a result of biochemical characterization and molecular cloning, five different 17 β -hydroxysteroid dehydrogenase isozymes have been identified to date. The type III 17 β -hydroxysteroid dehydrogenase isozyme, cloned by Andersson and Moghrabi (1997), catalyzes the biosynthesis of testosterone from androstenedione. A mutation involving the *HSD17B3* gene, mapped to chromosome 9q22, is responsible for male undervirilization. The type III isozyme is apparently expressed early in utero and is responsible for testosterone biosynthesis during the critical period of sexual differentiation, based on the observation that male adults homozygous for 17 β -hydroxysteroid dehydrogenase type III gene defects have ambiguous genitalia (Zhu et al, 1998).

The diagnosis is rarely made in the neonatal period. It may become apparent on discovery of a testis during a hernia repair in infancy or childhood. An hCG stimulation test resulting in an increased testosterone-to-androstenedione ratio would confirm the diagnosis and differentiate this condition from androgen insensitivity (Ahmed et al, 2000a). The primary management issue for patients with 17 β -hydroxysteroid oxidoreductase deficiency has been gender assignment. At this early stage, maintenance of the female sex of rearing with gonadectomy is usually elected. If the diagnosis is not made until puberty, when dramatic changes in virilization occur, certain families prefer a gender change to male. Cohen-Kettenis found gender role changes in 39% to 64% of 17 β -hydroxysteroid oxidoreductase deficiency patients raised as female (Cohen-Kettenis et al, 2005a). In an Arab cohort of 22 patients, Sobel and Imperato-McGinley (2004) noted 7 to undergo spontaneous gender role reversal to male without parental consent or psychiatric intervention. Traditionally, this decision has been strongly culturally influenced.

If a female sex of rearing is elected, gonadectomy, plastic reconstruction of the genitalia as necessary, and estrogen replacement therapy at puberty are indicated. For the patient maintained in the male gender, orchidopexy and reconstruction of the external genitalia are required. This entails hypospadias repair and chordee correction, which can be quite successful. However, phallic size remains small and infertility is the rule. Some have suggested that childhood treatment with intramuscular testosterone may result in a larger phallus (Sobel and Imperato-McGinley, 2004). Usually, endogenous androgen levels are adequate in the long term.

Two hypotheses have been proposed to explain the frequency of gender change from female to male with this enzyme deficiency, particularly among the cohort of Arab male pseudohermaphrodites with 17 β -hydroxysteroid dehydrogenase type III deficiency. One entails the potential male imprinting of the brain in utero as a result of the conversion of androstenedione to estrone; this theory is supported by studies in rats and rabbits demonstrating

that administration of estrogen or androstenedione is capable of inducing male sexual behavior (Reddy et al, 1974). The second is the possibility that 17 β -hydroxysteroid dehydrogenase activity is not deficient in the brain, its effect being mediated by the conversion of androstenedione to testosterone or estrogen (Imperato-McGinley et al, 1979a).

Androgen Receptor and Postreceptor Defects

Disorders of androgen receptor function represent the most common definable cause of 46,XY DSD or the undervirilized male. These patients characteristically have a 46,XY karyotype and testes and a spectrum of phenotypic abnormalities that vary from complete external feminization (syndrome of complete androgen insensitivity), to ambiguous genitalia (partial androgen insensitivity), to the phenotypically infertile male. Although the clinical presentations vary according to the severity of the disorder, the pathophysiology is similar (Wiener et al, 1997).

Syndrome of Complete (Severe) Androgen Insensitivity. The syndrome of complete androgen insensitivity is characterized clinically by a 46,XY karyotype, bilateral testes, female-appearing external genitalia, and absence of müllerian derivatives. Wilkins first suggested in 1950 that the clinical features of this syndrome were the result of androgen resistance. This condition has an incidence of 1 in 20,000 to 1 in 60,000 males, and it is transmitted as an X-linked trait.

The androgen receptor regulates the transcription of other specific genes, once activated by testosterone or DHT. This results in new mRNA synthesis from the downstream genes and protein production. The androgen receptor has been mapped to the X chromosome at Xq11-12, spanning 90 kb and comprising eight exons (Brown et al, 1989; Hiort and Holterhus, 2003). Males have only one copy of this gene. Point mutations of the gene account for more than 90% of cases of androgen insensitivity (Quigley et al, 1995). The identifiable molecular alterations of the androgen receptor gene cannot predict the resulting phenotype of the affected individual unless there is total loss of the receptor, which occurs in only 1% of all patients (Quigley et al, 1995).

Patients with complete androgen insensitivity have a normal female phenotype with the exception of diminished axillary and pubic hair. Their breast development and body habitus are feminine in character, and their external genitalia are unequivocally female, although the vagina is short and blind ending. It was previously believed that in utero resistance to testosterone action prevented stabilization of the wolffian ducts. Hannema and associates (2004), however, demonstrated wolffian duct derivatives in cases of complete androgen insensitivity. In 42% of patients, screening of the paratesticular area revealed well-developed epididymis and/or vasa deferentia. The mutations found in these patients entailed a single amino acid substitution in the androgen receptor ligand binding domain, rather than frameshift mutations, premature stop codons, or mutations in the DNA-binding domain, all of which were associated with absence of well-developed wolffian duct structures. These investigators suggest that mutant receptors with residual activity in vivo stimulate wolffian duct development. As a result, they should be classified as having *severe* rather than complete androgen insensitivity. Because the fetal testes secrete MIS, müllerian structures are absent. The testes may be found in the labia, inguinal canal, or abdomen.

These patients are rarely diagnosed in the neonatal period, unless a prenatal diagnosis is made on the basis of female phenotype and 46,XY karyotype on amniocentesis. With the increase in prenatal diagnostics, this is becoming a more common occurrence (Hughes and Patterson, 1994). More typically, however, the diagnosis is made as a result of primary amenorrhea or the finding of a testis at inguinal herniorrhaphy. Fifty percent of patients with complete (severe) androgen insensitivity syndrome have an inguinal hernia (Conte and Grumbach, 1989). Conversely, 1% to 2% of apparently female infants with inguinal hernia are found to have a 46,XY karyotype and complete androgen insensitivity syndrome (CAIS) (Wiener et al, 1997; Barthold et al, 2000). Therefore, routine

vaginostomy to confirm the presence of a cervix or endoscopy through a hernia sac to identify an intra-abdominal testis at the time of inguinal herniorrhaphy in female patients is a prudent maneuver. Histologically, the testes exhibit incomplete or absent spermatogenesis with normal or hyperplastic Leydig cells. They are comparable to immature, cryptorchid testes.

Endocrine evaluation in the neonatal period demonstrates normal male levels of testosterone, DHT, and gonadotropins. At puberty, gonadotropin levels rise, leading to increased levels of plasma estradiol, which results in feminization, including breast development.

Several types of mutant receptor abnormality that would account for this syndrome have been described, including (1) a decreased amount of apparently normal receptor; (2) absence of receptor binding; (3) a qualitatively abnormal receptor (thermolabile, or unstable); (4) other "receptor-positive" forms, including increased rate of dissociation of steroid receptor complex, defective upregulation of the androgen receptor, decreased affinity of ligand binding, and impaired nuclear retention of the ligand (Grumbach and Conte, 1998). In general, the severity of the defect in androgen receptor (quantity or quality) correlates with the phenotype. In addition, Hughes (2001) has noted the absence of coregulator proteins, without the absence of the androgen receptor, in cases of complete androgen insensitivity, suggesting that for androgen effects to be optimal an integrated array of transcriptional factors, coregulators, and ligands is required.

The diagnosis of complete (severe) androgen insensitivity may readily be made in the postpubertal patient on the basis of clinical and hormonal findings of amenorrhea, absence of pubic hair, or inguinal hernias containing testes. It is confirmed by a 46,XY karyotype and a normal male androgen and gonadotropin profile. Pelvic ultrasound examination confirms the absence of müllerian tissue, and a vaginal examination confirms a blind-ending vagina without a cervix.

In the prepubertal child, diagnosis is more difficult and requires an hCG stimulation test. Because of the time required for receptor binding quantification in genital skin, it is desirable to use PCR to characterize the androgen receptor gene in DNA obtained from a venous blood sample to detect a genetic marker for androgen insensitivity syndrome.

Management of complete (severe) androgen insensitivity relates primarily to the optimal timing of gonadectomy. Because the testes produce estradiol, which results in the appropriate changes for the female phenotype, it is considered by many preferable to leave the testes in situ until puberty is complete. Potential exceptions to the policy of delayed gonadectomy are palpable testes or testes associated with an inguinal hernia. One important caveat in deciding to leave the testes in situ is the need to confirm with absolute certainty that complete rather than partial androgen insensitivity exists by PCR characterization of the androgen receptor gene in venous blood DNA. If an incomplete form should exist, virilization at puberty could result (Batch et al, 1993). Another important consideration is the anticipated need to discuss with a postpubertal female the presence of testes that require removal, rather than doing so when the child is much younger and the psychosexual implications less charged. Because of the complexity of managing the CAIS patient, Hughes has advocated an individualized and holistic approach for each patient (Hughes et al, 2012).

A competing concern for retention of testicular tissue is the potential for malignant degeneration of the testes. In patients with complete androgen insensitivity who reach adulthood with a retained testis, the risk for development of a testis tumor—usually seminoma or gonadoblastoma—is thought to be 1% to 2%, only slightly higher than for a cryptorchid testis (Manuel et al, 1976; Müller and Skakkebaek, 1984). Before pubertal development the risk is extremely low, the youngest reported case of a germ cell tumor in an androgen insensitivity syndrome being in a 14-year-old (Ahmed et al, 2000b). Therefore, in general, delayed gonadectomy after puberty is believed to be safe (Cools et al, 2006).

After orchiectomy, cyclic estrogen-progestin therapy is begun. The majority of patients have successful treatment of their short

vagina with progressive dilation (Ismail-Pratt et al, 2007). Some patients may benefit from vaginoplasty (Boehmer et al, 2001). Currently, all studies of patients with complete androgen insensitivity support an unequivocal female gender identity, consistent with androgen resistance of brain tissue as well. In one study, no statistical differences were found between the complete androgen insensitivity group and normal controls in any quality-of-life or gender-related behavior criterion (Hines et al, 2003). To date, there has been no report of a patient with complete androgen insensitivity raised as a female who needed gender reassignment to male (Meyer-Bahlburg, 1999). In any event, age-appropriate psychological counseling is an important component of management in the androgen insensitivity syndromes.

Syndrome of Partial Androgen Resistance. The syndrome of partial androgen resistance includes syndromes that were once thought to represent separate entities: Reifenstein, Gilbert-Dreyfus, Rosewater, and Lubs syndromes (Griffin, 1992). These are X-linked disorders of incomplete masculinization that represent a spectrum of phenotypic abnormalities. The major finding is ambiguity of the external genitalia to varying degrees. The partial form of androgen insensitivity may be expressed variably even within the same family. The classic phenotype is that of a male with perineoscrotal hypospadias, cryptorchidism, rudimentary wolffian duct structures, gynecomastia, and infertility. However, the phenotypic spectrum can range from hypospadias and a pseudovagina to gynecomastia and azoospermia (Wilson et al, 1974). The differential diagnosis includes 5 α -reductase deficiency and 17 β -hydroxysteroid dehydrogenase. The endocrine profile of partial androgen insensitivity syndrome (PAIS) is similar to that of CAIS. At puberty, gynecomastia may develop. The phallus may enlarge slightly, but it remains small.

To date, over 800 mutations in the androgen receptor gene have been discovered (Hughes et al, 2012). It has been well recognized in PAIS that these mutations produce a diversity of phenotypes between and within affected families, consistent with additional factors that modulate responsiveness to androgen. This seems consistent with prior studies in the 1980s on genital skin fibroblasts, demonstrating two forms of receptor defect in PAIS: (1) a reduced number of normally functioning androgen receptors and (2) a normal receptor number but decreased binding affinity (Griffin and Durrant, 1982; Hughes, 2000).

The diagnosis of PAIS can be difficult. In the neonatal period, it may be made in the setting of a 46,XY karyotype, ambiguous external genitalia, and absent müllerian structures on pelvic ultrasound. Endocrine evaluation confirms normal male levels of testosterone and gonadotropins, and a normal testosterone/DHT ratio. An hCG stimulation test and characterization of the androgen receptor gene in serum DNA by PCR should confirm the diagnosis. A family history consistent with X-linked inheritance of ambiguous genitalia is of great assistance. A course of androgen injections in early infancy is often used to assess androgen responsiveness, which can aid in gender assignment.

Management must be individualized depending on the degree of genital ambiguity. In patients assigned a female gender, gonadectomy and surgical reconstruction of the external genitalia are indicated; at puberty, estrogen-progestin replacement is instituted. The majority of PAIS patients raised as males require treatment of cryptorchidism, reduction of gynecomastia, and genital reconstruction. Phallic size remains small, however, and the effects of supraphysiologic doses of testosterone have been disappointing (Migeon et al, 1994). A study by Szafran suggested a novel high content analysis (HCA) approach to study androgen receptor function at a single cell level in genital fibroblasts (Szafran et al, 2009). This could help individualize medical therapy. The risk of gonadal tumor is somewhat higher than in CAIS (up to 15%), and there is an increased risk of male breast cancer with PAIS (Cools et al, 2006; Hughes, 2006). Of importance in considering gender assignment in patients with partial androgen insensitivity is the recognition that the receptor defect affecting the external genitalia appears to affect brain receptors for testosterone similarly. Unfortunately, because of the distinct phenotypic variability, even within families, gender

assignment of patients with PAIS cannot be based on the specifically identified androgen receptor gene (Boehmer et al, 2001). The study by Melo and colleagues (2003) of 11 patients with PAIS (5 raised female, 6 raised male) demonstrated gender of rearing to be consistent with adult gender role. This suggests the possibility that in the setting of inadequate androgen imprinting of the fetal brain, sex of rearing may predominate in determination of gender identity. Unfortunately, this has not consistently proven to be the case.

Unfortunately, long-term outcome data in the management of patients with PAIS are limited. Migeon and colleagues' study (2002) of 14 patients with PAIS noted that 23% were dissatisfied with neonatal gender assignment irrespective of current status as male or female. Another study of 15 postpubertal males with PAIS documented major impairment in sexual function in all (Bouvattier et al, 2006). However, Mazur (2005) found that only 9% of patients with PAIS self-initiated a gender reassignment.

The current recommendation for PAIS is to allow virilization of the external genitalia to serve as a guide in gender assignment, in that this may be the best means of assessing androgen imprinting of the brain, for lack of a more precise marker (Sobel and Imperato-McGinley, 2004).

Mild Androgen Insensitivity Syndrome. A relatively new classification is that of mild androgen insensitivity syndrome discovered in the course of investigations for male factor infertility. Recent studies have demonstrated a variety of mutations, usually quite discrete within the androgen receptor gene, to account for the infertility (Hiort and Holterhus, 2003). Men with this syndrome may be normal phenotypically or have a history of mild hypospadias repair but are azoospermic or severely oligospermic. They have been found to have normal to elevated serum testosterone levels with normal to elevated LH levels. This suggests that infertility in otherwise normal males may be the clinical manifestation of partial androgen insensitivity, representing the far end of a variable phenotypic spectrum. To date, the pathophysiology of the abnormal spermatogenesis caused by androgen receptor mutations remains unknown (Hiort and Holterhus, 2003).

5 α -Reductase Deficiency

The disorder of 5 α -reductase deficiency is one of the most fascinating forms of male undervirilization. The clinical presentation of this enzyme disorder was actually predicted in 1972, before the description of such patients in 1974 by Walsh and Imperato-McGinley and their colleagues (Wilson, 1972; Imperato-McGinley et al, 1974; Walsh et al, 1974). Extensive characterization of the disease has been achieved since that time.

5 α -Reductase is a microsomal enzyme that catalyzes the conversion of testosterone to DHT. The condition is transmitted in an autosomal recessive pattern, and only homozygous males are affected. Two 5 α -reductase genes have been cloned; they encode different isoenzymes. The type 1 isoenzyme, encoded on chromosome 5, is expressed in low levels in the prostate and external genitalia. The type 2 isoenzyme is encoded on chromosome 2 and is expressed in high levels in the prostate and external genitalia (Thigpen et al, 1992b). Male undervirilization caused by 5 α -reductase deficiency is secondary to mutations in the type 2 gene. At least 68 mutations have been identified (Thigpen et al, 1992a; Imperato-McGinley, 2002; Berra et al, 2011). Identical mutations in individuals with widely different geographic and ethnic backgrounds support the concept of mutational "hot spots" on the gene.

On presentation individuals with this disorder are neonates with a 46,XY karyotype and a phenotype that may vary from normal female to markedly ambiguous genitalia (more common) to penoscrotal hypospadias to the rare, isolated microphallus (Maimoun et al, 2011). Typically the phallus is quite small, appearing as a normal or enlarged clitoris (Fig. 150-22). A urogenital sinus is present, with convergence of vaginal and urethral channels, and there is labioscrotal fusion (Fig. 150-23). The vaginal pouch is short and blind ending. Testes and epididymides are located in the labia, inguinal canals, or abdomen; and the vasa terminate in the

Figure 150-22. External genitalia of patient with 5 α -reductase deficiency. Note clitoromegaly with marked labioscrotal fusion and small vaginal introitus. (From Diamond D. *Intersex disorders: I and II*. AUA Update Series, vol. IX, lessons 9 and 10. Houston: American Urological Association Office of Education; 1990.)

blind-ending vaginal pouch. At puberty, partial masculinization occurs with an increase in muscle mass, development of male body habitus, increase in phallic size, and onset of erections (Peterson et al, 1977). Sperm production and fertility in affected individuals have been reported (Imperato-McGinley et al, 1982; Zhu et al, 1998). Other secondary sexual characteristics, including enlargement of the prostate and hairline recession, do not develop. Recently, the recognition of the rare 5 α -reductase patient with a female phenotype suggestive of CAIS has been made (Maimoun et al, 2011).

On endocrine evaluation these individuals have elevated mean plasma testosterone but low DHT levels. After hCG stimulation, the testosterone-to-DHT ratio increases to greater than 20:1. Genital skin fibroblast cultures demonstrate diminished to absent 5 α -reductase activity (Migeon et al, 1994). At puberty, virilization is presumed to occur because the androgen receptor binds markedly higher levels of testosterone at low affinity or because of the normal increase at puberty in the activity of the 5 α -reductase type 1 isoform, resulting in sufficient DHT for virilization (MacLaughlin and Donahoe, 2004). Indeed, the enzyme abnormalities in this disorder have been shown to be biochemically heterogeneous, ranging from reduced affinity of the enzyme for testosterone and reduced affinity for NADPH to altered pH activity profiles (Kupfer et al, 1992). The diagnosis is confirmed by sequencing the entire 5 α -reductase type 2 (*SRD5A2*) gene.

The phenotypic characteristics of this disorder have helped to clarify the roles of testosterone and DHT in normal development. Although DHT appears to be critical for the development of normal external genitalia in utero, testosterone alone appears sufficient for wolffian duct development.

Individuals in the pedigree studied by Imperato-McGinley and colleagues in the Dominican Republic underwent gender reversal at puberty and were known within the community as *guevedoces* ("penis at 12") (Imperato-McGinley et al, 1979b). This strong tendency toward reversal of gender identity in 5 α -reductase deficiency has been one of the most intriguing aspects of the disorder. It has

Figure 150-23. Unusual presentation of patient with 5 α -reductase deficiency with normal female external genitalia. A, Intraoperative examination of external genitalia; note enlarged clitoris, common urogenital sinus, and posterior labioscrotal fusion. B, Palpable testes exposed through labioscrotal incisions. C, Cystoscopic examination of vaginal channel revealing a blind-ending pouch and absent cervix.

lent support to the concept that testosterone exerts the primary male imprinting effect on the brain. However, the discovery that there are two isoenzymes for 5 α -reductase, only type 2 being deficient in this syndrome, allows for the possibility that 5 α -reductase type 1 has some impact on the brain (Thigpen et al, 1992b). As a

result, with early diagnosis of 5 α -reductase deficiency, a male gender assignment is generally favored, bearing in mind that the studies strongly supporting male gender identity in this disorder were performed in sociologically unique environments (Zhu et al, 1998). Cohen-Kettenis (2005a) noted 56% to 63% of 5 α -reductase deficiency patients to undergo gender reversal from female to male. The clinician must be open to familial cultural considerations regarding the value of male gender as well as the significance of penile size. In the setting of male gender assignment, cryptorchidism and hypospadias should be surgically corrected. Fertility is possible, particularly with the advent of intrauterine insemination (Katz et al, 1997). Exogenous DHT could be used at puberty in an attempt to promote phallic growth, but it would be likely to impair spermatogenesis. For some individuals with an unambiguously female phenotype (Fig. 150-24) or extremely small phallic size, female gender may be assigned. For these patients, gonadectomy should be performed as early as possible and certainly well before puberty to prevent virilization. Estrogen and progestin should be administered at the expected time of puberty. Vaginoplasty and clitoral reduction may be performed within the first year of life in those with a severe defect to provide for normal appearance of the external genitalia and to allay parental anxiety.

Persistent Müllerian Duct Syndrome

Persistent müllerian duct syndrome (PMDS), or *hernia uteri inguinalis*, the term originally used by Nilson (1939), characteristically describes a group of patients with a 46,XY karyotype and normal male external genitalia but internal müllerian duct structures. Typically, these phenotypic males have unilateral or bilateral undescended testes, bilateral fallopian tubes, a uterus, and an upper vagina draining into a prostatic utricle. The condition is commonly diagnosed after müllerian tissue is encountered during inguinal herniorrhaphy or orchidopexy.

Clarnette and coworkers (1997) suggested three categories for patients with PMDS: (1) the majority (60% to 70%) with bilateral intra-abdominal testes in a position analogous to ovaries; (2) a smaller group (20% to 30%) in which one testis is found in a hernia sac or scrotum in association with a contralateral inguinal hernia (the classic presentation of hernia uteri inguinalis); and (3) the smallest group (10%), in which both testes are located in the same hernia sac (as a result of transverse testicular ectopia) along with the fallopian tubes and uterus. Indeed, PMDS is believed to be etiologically important in transverse testicular ectopia, occurring in 30% to 50% of cases (Fujita, 1980).

The MIS gene was cloned in 1986 and localized on the short arm of chromosome 19 (Cates et al, 1986). It shows homology with the TGF- β superfamily of growth and differentiation factors (Imbeaud et al, 1995). PMDS is thought to be a heterogeneous disorder genetically in which some subjects have a defect in the gene for MIS located on chromosome 19p13 and others have a defect in the gene for its type II receptor located on chromosome 12q13 (MacLaughlin and Donahoe, 2004). The condition may occur sporadically or may be inherited as an X-linked (or autosomal dominant, sex-limited) trait (Migeon et al, 1994).

The treatment of PMDS is relatively straightforward, in that all patients are phenotypic males who require orchidopexy. The cases of adult patients with associated testis tumor (most commonly seminoma) probably reflect the increased risk of malignancy in intra-abdominal undescended testes. One treatment caveat relates to management of the rudimentary müllerian structures. The vasa deferentia are in close proximity to the uterus and proximal vagina, and historically preservation of the necessary müllerian structures to avoid injury to the vasa was recommended to preserve fertility (Sloan and Walsh, 1976). Eleven malignancies have now been reported in retained müllerian remnants, consistent with a risk of 3% to 8%, supporting careful surgical excision, which can be performed laparoscopically (Farikullah et al, 2012).

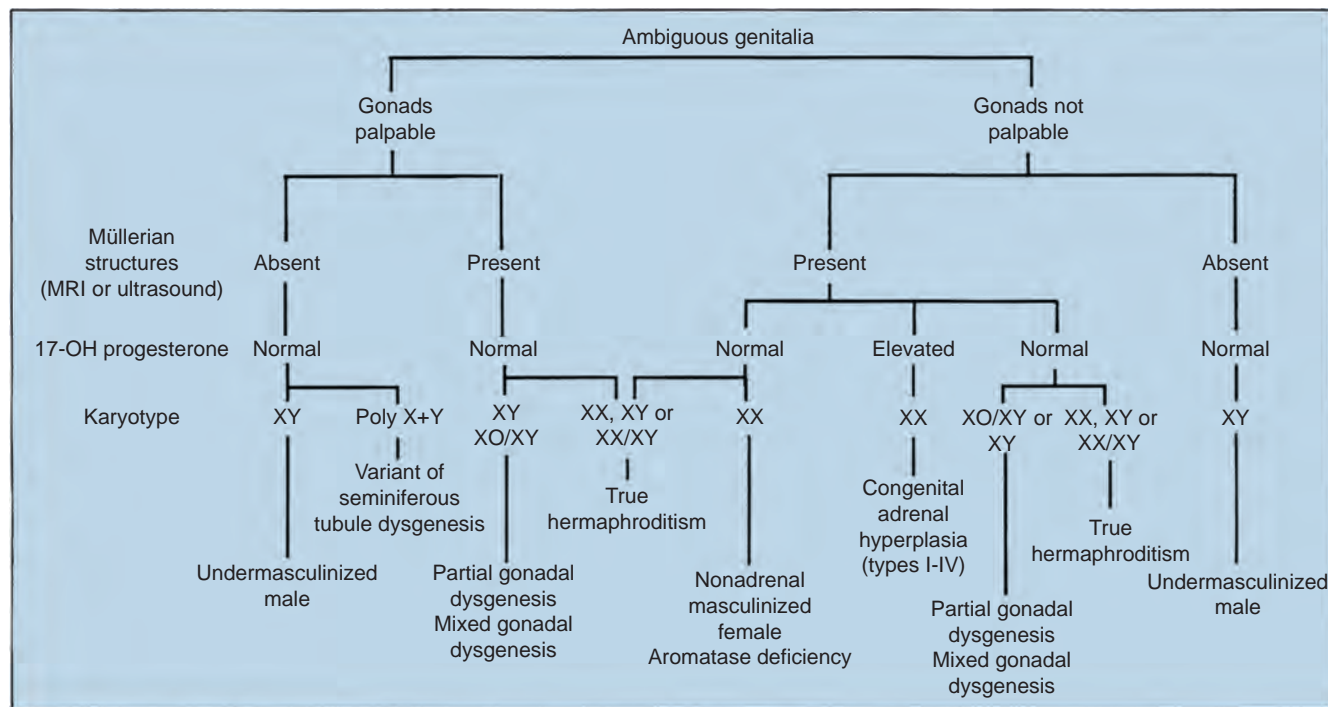

Figure 150-24. Diagnostic algorithm for a newborn with ambiguous genitalia based on gonadal palpability, presence or absence of müllerian structures, 17-hydroxyprogesterone concentration, and karyotype. MRI, magnetic resonance imaging (Modified from Grumbach MM, Conte FH. Disorders of sex differentiation. In: Wilson JD, Foster DW, editors. Williams textbook of endocrinology. Philadelphia: Saunders; 1998. p. 1401.)

Unclassified Forms: Mayer-Rokitansky-Küster-Hauser Syndrome

The Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome is a rare disorder entailing congenital absence of the uterus and vagina. It occurs in approximately 1 of every 4000 to 5000 female births. Patients with MRKH syndrome have a 46,XX karyotype and are normal-appearing females with normal secondary sex characteristics. The external genitalia appear normal, but only a shallow vaginal pouch is present. In the typical form of the syndrome there is symmetrical anatomy with absence of both vagina and uterus. Normal ovaries and fallopian tubes are present, and ovarian function is normal, but only symmetrical uterine remnants are found (Griffin et al, 1976). The report of a *WNT4* mutation in a woman with a phenotype resembling MRKH suggests the importance of this gene in müllerian duct formation (Biason-Lauber et al, 2004).

The most common clinical presentation for MRKH syndrome is primary amenorrhea, but patients may have infertility or dyspareunia. Upper urinary tract anomalies occur in approximately one third of patients and include renal agenesis, pelvic kidney, and horseshoe kidney.

Atypical forms of MRKH syndrome have been described in up to 10% of patients, in which asymmetrical uterine remnants and/or aplasia of one or both fallopian tubes is discovered. As a result, endometrial tissue or variable development of the uterus with hematometra may be present, resulting in a clinical presentation with cyclic abdominal pain. Urinary tract anomalies occur more commonly in patients with the atypical form of MRKH. In a study of 100 patients with MRKH syndrome, 38 of 56 patients (68%) with the atypical form of the condition had upper urinary tract abnormalities. None of the 44 patients with the typical form of MRKH syndrome had an upper urinary tract anomaly (Strubbe et al, 1994). In addition, associated cardiac anomalies have been noted in 16% of MRKH patients (Pitcock et al, 2005).

A radiologic evaluation with ultrasonography and magnetic resonance imaging may define müllerian anatomy accurately in MRKH and distinguish between typical and atypical forms of the disorder (Nussbaum-Blask et al, 1991; Reinhold et al, 1997).

Treatment entails creation of a neovagina, by means of dilation or surgically, to allow for sexual function (Ismail-Pratt et al, 2007). Given the frequent success of dilation and its comparable functional outcomes to surgery, it should be the first line of therapy as recommended by the American College of Obstetricians and Gynecologists (Gargollo et al, 2009; Morcel et al, 2013). If present, a hemiuterus should be removed, whereas a midline uterine structure should be hormonally suppressed rather than connecting this structure to a reconstructed vagina.

EVALUATION AND MANAGEMENT OF THE NEWBORN WITH AMBIGUOUS GENITALIA

The evaluation and initial management of the neonate with ambiguous genitalia must be regarded as a medical and psychosocial emergency and be handled with great sensitivity toward the family. Ideally, a medical team including a pediatric urologist, an endocrinologist, and a psychiatrist or psychologist experienced in managing intersex patients should work closely with the family. The team's goal should be to make a precise diagnosis of the disorder (which can be achieved in most cases) and, with the involvement of the parents, to assign a proper sex of rearing based on the diagnosis, the status of the child's anatomy, and the functional potential of the genitalia and reproductive tract.

In obtaining the history, certain pieces of information may be particularly valuable. A history of infant death within the family might suggest the possibility of CAH, and infertility, amenorrhea, or hirsutism might also suggest possible familial patterns of intersex states. Certainly, maternal use of medications, in particular steroids or contraceptives, during the pregnancy is of great importance.

The critical finding on physical examination is the presence of one or two gonads. This finding effectively rules out overmasculinization of the female. Because ovaries do not descend, a distinctly palpable gonad along the pathway of descent is highly suggestive of a testis. Rarely, an ovotestis undergoes descent to the inguinal canal and may be suspected on the basis of asymmetry of tissue texture of the poles of the gonad. This suspicion may be further supported by ultrasound findings. The patient with bilaterally impalpable testes or a unilaterally impalpable testis and hypospadias should be regarded as having a DSD until proven otherwise, whether or not the genitalia appear ambiguous. Kaefer and associates (1999) studied the incidence of DSDs in patients with cryptorchidism and hypospadias and without ambiguous genitalia. With a unilateral cryptorchid testis, the incidence of DSD was 30% overall—15% if the undescended testis was palpable and 50% if it was impalpable. In the setting of bilateral undescended testes and hypospadias, the incidence of DSD was quite similar—32% overall but only 16% if both gonads were palpable. If one of two undescended testes was impalpable, the incidence of DSD tripled to 47%, comparable to the rate in those with a unilateral, impalpable, cryptorchid testis. In addition, posterior urethral meatal position was noted to be a strong predictor of DSD in this group of patients—65%, versus 5% to 8% with a midshaft to anteriorly located hypospadiac meatus (Kaefer et al, 1999).

In addition to gonadal examination, penile size should be assessed and an accurate measure of stretched penile length recorded. The mean stretched penile length in full-term males born in the United States is 3.5 cm (± 0.04) (Lee et al, 2006).

An additional important finding on physical examination is the presence of a uterus, which is noted as an anterior midline cordlike structure on rectal examination. A more precise means of assessing müllerian anatomy is by pelvic ultrasonography, which may be performed immediately in the neonatal period. In addition to defining müllerian anatomy and confirming the presence or absence of a uterus, the gonads and adrenals should be studied. Normal anatomy of an undescended gonad should be confirmed, and a cyst within the gonad, consistent with ovotestis, should be ruled out.

Within the immediate neonatal period, a karyotype should be obtained. Typically this requires 2 days to perform. Therefore an attractive approach to obtain chromosomal data quickly is FISH, which rapidly identifies X and Y chromosomes. It is typically used to confirm the presence of a second X chromosome. The technique is much more rapid than karyotyping, producing results within a few hours.

Serum studies should be immediately sent to rule out a salt-wasting form of CAH. In addition to serum electrolytes, testosterone and DHT should be measured early. Migeon and colleagues (1994) emphasized that the androgen levels may drop quickly, necessitating early study. In addition, they suggested that serum 17-hydroxyprogesterone should not be measured until day 3 or 4 to rule out 21-hydroxylase deficiency, because the stress of delivery may result in physiologic elevation of this steroid precursor in the first 1 or 2 days of life.

In the absence of palpable testes, the presence or absence of testicular tissue should be determined by documentation of a markedly elevated LH level, consistent with anorchia, or by means of an hCG stimulation test, which can demonstrate normally functioning testicular tissue (Jarow et al, 1986). In addition to ruling out anorchia, the study can enable diagnosis of 5 α -reductase deficiency (by virtue of an increased ratio of testosterone to DHT) and can help distinguish between impaired testosterone synthesis (deficient response to hCG) and androgen insensitivity (normal response to hCG). Serum MIS measurement should be included as a marker of the presence of testicular tissue (Hughes et al, 2012).

Based on physical examination findings (largely, gonadal palpability), the presence or absence of müllerian structures on ultrasonography, 17-hydroxyprogesterone concentration, and the karyotype, a reasonable differential diagnosis may be formulated (Fig. 150-25). A precise diagnosis can virtually always be achieved for the 46,XX DSD (overvirilized female) but in only 50%

Karyotype

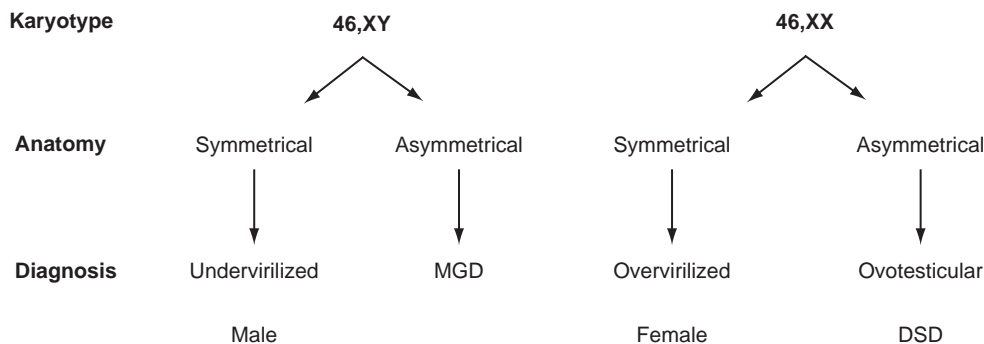

Figure 150-25. Likely diagnoses based on karyotype and anatomic symmetry. DSD, disorder of sex differentiation; MGD, mixed gonadal dysgenesis.

KEY POINTS: EVALUATION AND MANAGEMENT OF DISORDERS OF SEX DEVELOPMENT

- The team's goals should be to make a precise diagnosis of DSD (which can be achieved in most cases) and, with the involvement of the parents, to assign a proper sex of rearing based on the diagnosis, the status of the child's anatomy, and the functional potential of the genitalia and reproductive tract.
- The patient with bilaterally impalpable testes or a unilaterally impalpable testis and hypospadias should be regarded as having a DSD until proven otherwise, whether or not the genitalia appear ambiguous.

of 46,XY DSD undervirilized males (Lee et al, 2006). The presence of asymmetrical anatomy on examination and ultrasonography is an important observation and suggests mixed gonadal dysgenesis if the karyotype is 46,XY and ovotesticular DSD if it is 46,XX.

Performance of laparotomy or laparoscopy and gonadal biopsy is usually the next definitive clinical step required when a firm diagnosis based on the aforementioned data is impossible. **Laparotomy or laparoscopy in this setting remains a diagnostic maneuver; removal of gonads or reproductive organs should be deferred until the final pathology report is available and a gender has been assigned.** PCR characterization of the androgen receptor in venous blood DNA may define the precise genetic abnormality responsible for a given DSD, be it abnormal androgen receptor or an enzyme abnormality. These studies should be performed in specialized laboratories where normal values are well established.

Finally, anatomic definition of the urogenital sinus and ductal structures contributes to the correct diagnosis and is necessary before any surgical intervention. The urogenital sinus is well imaged by retrograde contrast injection, which also opacifies ductal structures, defines the entry of urethra and vagina into the sinus, and outlines the cervical impression within the vagina. Endoscopy can define these relationships further but is usually not necessary until surgical reconstruction becomes imminent.

Gender Assignment

After a definitive diagnosis has been reached, a thorough and candid discussion with the family regarding gender assignment should take place. **Issues related to the diagnosis-specific potential for normal sexual functioning and fertility and the risk of gonadal malignancy should be addressed.** Parents should understand that high-quality data regarding the long-term psychosocial outcomes of gender assignment for the majority of DSDs are lacking, although longitudinal studies are being pursued. Parental involvement in the decision-making process is essential. If the diagnosis of a DSD is made prenatally, it is important to present a plan

of management to the parents or risk termination of the pregnancy (Nihoul-Fekete, 2004).

In the setting of a 46,XX karyotype and masculinized female, gender assignment is usually appropriately female. In CAH, cortisol suppresses the undesired androgen; and if maternal androgen is responsible for virilization, its discontinued stimulation is corrective. In both cases there are normal ovaries and müllerian ducts, and a normal reproductive potential exists. **If the karyotype is 46,XY, the issue is a more complex one and includes factors such as penile length and evidence of androgen insensitivity.** For example, 46,XY patients with complete (severe) androgen insensitivity are appropriately assigned a female gender, whereas those with 5 α -reductase deficiency may be more appropriately assigned a male gender. The most frequent abnormal karyotype is 45,X/46,XY mosaicism, which has a variable phenotypic spectrum. The degree of masculinization of the external genitalia appears to vary with the amount of testicular tissue present, and gender assignment depends on the functional potential of the gonadal tissue, reproductive tracts, and genitalia. The best predictor of adult gender identity is initial gender assignment (Cohen-Kettenis, 2005b). Some investigators have suggested deferring the issue of gender assignment until patients reach an age at which they may declare their own gender identity. Such an approach, although rational, is difficult to implement given cultural norms and not recommended in the consensus statement (Lee et al, 2006). As Elliott (1998) states, "We treat these children the way we do (as male or female) because this is the way we see the world; most importantly it is the way that the children, themselves, are taught to see the world."

Overall, it is well to remember in the management of ambiguous genitalia the parameters of optimal gender policy outlined by Meyer-Bahlburg (1998):

- Reproductive potential (if attainable at all)
- Good sexual function
- Minimal medical procedures
- An overall gender-appropriate appearance
- A stable gender identity
- Psychosocial well-being

The importance of transparency with the family and patient in management of DSDs cannot be overemphasized. Uncertainties in outcomes with different gender assignment for different disorders mandate involvement of the parents in early decision making. In the long run, transparency is essential for a healthy physician-patient relationship as the child develops into adolescence and adulthood, affording them knowledgeable engagement in DSD management for the long term.

Ultimately, management of patients with disorders of sexual differentiation remains a challenging and humbling process. On the one hand, physicians have at their disposal sophisticated molecular biologic techniques that have enabled them to identify genetic disorders responsible for the majority of DSDs. On the other hand, the mysteries of brain dimorphism in the setting of sexual ambiguity remain to be solved to optimize the long-term psychosocial outcome of gender assignment for the individual patient.

151 Surgical Management of Disorders of Sex Development and Cloacal and Anorectal Malformations

Richard C. Rink, MD, FAAP, FACS

Classification of Urogenital Sinus and Cloacal Anomalies

Surgical Reconstruction of Disorders of Sex Development and Urogenital Sinus

Surgical Reconstruction for Cloacal Malformations

Summary

The surgical management of disorders of sex development (DSD) and cloacal anomalies is one of the most complex problems a pediatric urologist/surgeon will ever encounter. The vast majority of children with DSD will be noted to have some genital ambiguity. Surgery in this group is perhaps the most controversial topic addressed in this entire textbook. The complexity of this topic has led to featured presentations by nearly every major television and print media outlet. Having a child born with DSD is very stressful for the parents and it is therefore imperative to create a supportive medical team that can not only help the family understand the diagnosis but also help them understand all controversies and options they have for medical and surgical management. Most families historically have opted for early surgery to “normalize” their child’s genitalia. The thought of “doing nothing” for their child with DSD has been noted to be stressful for families (Creighton et al, 2012). Most parents viewed surgery as obvious and necessary and something that did not involve decision making (Crissman et al, 2011). However, Lloyd and colleagues (2005) and Akbiyik and Kutlu (2010) have now shown there to be tremendous variability in genital proportions of “normal” adults and children who do not have a DSD. The family should also be informed of the possible long-term psychosocial experience of the child with DSD (Krishnan and Wisniewski, 2014). What is clear is that the parents must be made aware of all pros and cons of having surgery and also of not having surgery. **No parent or child should ever be talked into having surgery.** However, if surgery is elected the multidisciplinary medical team should be supportive of the family and should make sure the parents are aware of the options for timing of the surgery and the advantages and disadvantages for each surgical option. The parents should also be made aware of and have access to support groups such as the CARES Foundation (www.caresfoundation.org), Accord Alliance (accordalliance.org), and Magic Foundation (magicfoundation.org). This chapter addresses the surgical options and management of this complex spectrum of anomalies with the assumption that the parents and family agree that surgery is appropriate.

CLASSIFICATION OF UROGENITAL SINUS AND CLOACAL ANOMALIES

Because of the spectrum and complexity of urogenital sinus anomalies and the potential for other associated organ system abnormalities, evaluation and management must be meticulous. In urogenital sinus anomalies there is a persistent communication of the vagina with the urinary tract. Communication of the vagina with the urinary tract may occur at any point from the urethral meatus to the bladder, but the majority occur within the mid to distal portion of the urethra. The two structures join and exit on the perineum as a single common urogenital sinus channel.

A persistent urogenital sinus is seen in four entities. Most commonly it occurs in **genital ambiguity states**, most frequently with congenital adrenal hyperplasia (CAH) (Fig. 151-1). It can also occur as a **pure urogenital sinus** with normal external genitalia (Fig. 151-2). In **persistent cloacal anomalies** there is the added complexity of rectal involvement, with all three systems—genital, urinary, and intestinal—exiting as an isolated single perineal opening. More recently, **female exstrophy** has been thought to represent a form of persistent urogenital sinus (Adams, 2000).

Early descriptions of this confluence were based on previous medical training. Urologists described the vagina as entering the urethra, whereas gynecologists noted that the urethra entered the vaginal vestibule (Jones and Jones, 1954). Jaramillo and colleagues (1990) noted that on examination the external cloacal orifice appears vaginal in nature in some cases but in others appears more like a normal urogenital orifice (Figs. 151-3 and 151-4). **Regardless of how the confluence of the urinary and genital tracts is described, the confluence location in relation to the bladder neck is a more critical factor in surgical management than the length of the common channel** (Rink et al, 2005a).

Evaluation

Urogenital sinus abnormalities are most often seen in DSD states, most commonly in association with CAH, which has been

KEY POINT: UROGENITAL SINUS ANOMALIES—GENERAL

- Urogenital sinus anomalies are found in four entities: genital ambiguity states, pure urogenital sinus, persistent cloaca with rectal involvement, and female exstrophy.

noted to have an incidence as high as 1 in 500 in the nonclassic, mild form (Hughes, 1988). CAH is a group of inherited autosomal recessive genetic abnormalities of which the most common enzymatic defect resulting in genital ambiguity is 21-hydroxylase deficiency. This occurs in approximately 1 in 15,000 to 16,000 persons (Speiser and White, 2003; Merke and Bornstein, 2005). Mutations in the 21-hydroxylase gene (mutation in *CYP21A2* gene on the short arm of chromosome 6 in 90% to 95% of individuals) result in varying degrees of virilization corresponding to the type of mutation. CAH should be regarded as a spectrum disorder from mild

anomalies to those with deep impact on life (Nordenskjöld et al, 2008). Therefore initial management must focus on making an accurate diagnosis to allow proper gender identification. Every effort should be made to establish the genetic sex within 48 hours. Children with CAH require careful monitoring of fluid and electrolytes because 67% to 75% will have significant salt wasting owing to lack of aldosterone secretion (Speiser and White, 2003; Merke and Bornstein, 2005). The classic findings of salt wasting in 21-hydroxylase deficiency are hyponatremia, hyperkalemia, high urinary sodium, low serum and urinary aldosterone, and elevated plasma renin activity (New et al, 2014). This may lead to dehydration, poor feeding, hypotension, and even vascular collapse, shock, and death (adrenal crisis). Evaluation should include rapid karyotyping of cultured peripheral leukocytes, measurement of serum electrolyte levels, and determination of hormonal levels for CAH. All results are shared with the gender assignment team, which includes the parents, pediatric endocrinologist, pediatric urologist, neonatologist, geneticist, child psychiatrist/psychologist, and often clergy. The child should not be named until sex assignment is complete (Rink and Adams, 1998).

Cloacal anomalies are a much more complex problem involving multiple organ systems, but fortunately they occur in only 1 in every 40,000 to 50,000 patients (Karlin et al, 1989). They are the most challenging of the anorectal malformations and make up 13.6% of this group (Fleming et al, 1986). These children have a very broad spectrum of findings on examination of the external genitalia. Some may have a prominent phallic structure and also initially require evaluation for a DSD.

History and Physical Examination

Many children with urogenital sinus abnormalities are now identified by antenatal ultrasonography, with the findings of fluid-filled pelvic structures (vagina and bladder) with indeterminate genitalia. Furthermore, since 2009 newborn CAH screening programs have been carried out in all 50 states and in areas worldwide, which helps to identify some affected children (New et al, 2014). However, the history and the physical examination remain extremely helpful in cases of genital ambiguity and can often lead to the diagnosis itself. It is critical to determine whether the mother ingested any medications during pregnancy, especially androgenic substances. A family history of early infant death or fluid and electrolyte abnormalities suggests CAH. Have other children had genital ambiguity or gender dysphoria at puberty? Notation should be made of any family members with abnormal pubertal development.

The physical examination can at times be very useful in determining the appropriate gender and in helping to identify other organ systems involved. A general evaluation of the child's overall health should be completed before focusing on the genital examination. Abnormal facies suggesting a syndrome should be noted. Hypertension can occur in children with genital ambiguity secondary to CAH from 11 β -hydroxylase deficiency. Therefore blood pressure should be documented. Evidence of dehydration may also lead to a diagnosis of CAH. On abdominal examination a mass, particularly a suprapubic mass, may be present because of a distended bladder or hydrometrocolpos, or both. Hydrometrocolpos is frequently an initial sign and is often the only early finding in pure urogenital sinus abnormalities.

In cloacal anomalies, abdominal distention may be severe secondary to hydrometrocolpos and bladder and intestinal distention. Hydrometrocolpos was noted commonly in early series (Chappell and Bleloch, 1973; Klugo et al, 1974); its incidence ranged from 29% of Peña's patients (Peña, 1989) to 63% of those reported by Bartholomew and Gonzales (1978). It is caused most commonly by preferential flow of urine through the urogenital sinus into the vagina (or vaginas) with voiding and associated poor vaginal drainage. Maternal estrogen stimulation of the cervical glands results in mucus production, thereby further adding to the distention. Urine flow can occur into the rectum also. The distention of these pelvic structures has resulted in edematous, cyanotic legs and respiratory distress, as well as acidosis (Raffensperger, 1988).

The lower part of the back should be examined to identify any evidence of spinal cord abnormalities, which can be associated with urogenital sinus abnormalities and are very common with cloacal anomalies. Such abnormalities may take the form of a sacral dimple, hair patch, or area of abnormal pigmentation, but more commonly there is evidence of a bone abnormality, such as an abnormal buttock crease or flattened buttocks as a result of sacral agenesis.

Genital examination should note the size of the phallus and the consistency of the erectile bodies. Any degree of curvature should be documented. Huffman (1976) multiplied the width of the glans times the length of the phallus to determine the "clitoral index," which he noted should be less than 3.5 mm to be normal and was of concern when greater than 10 mm. The average clitoral length for a full-term girl in the United States was noted to be 4.0 ± 1.24 mm and the average width was 3.32 ± 0.78 mm (Hughes et al, 2006). Persistent isolated clitoral hypertrophy may be found in premature infants and is not associated with DSD or other signs of ambiguity (Williams et al, 2013). The location of the meatus of

the urogenital sinus should be noted and may occur in a spectrum from a near-normal introital location to the tip of a well-formed glans. The gonads should be sought and, when found, their number, location, and consistency should be noted. If both gonads are descended, it is extremely unlikely that a 46,XX chromosome makeup will be found. The labioscrotal folds should be examined for their relationship to the phallus and rectum, as well as for the degree of fusion. Increased pigmentation of the labioscrotal folds and areola may be seen in some cases of CAH as a result of increased levels of melanocyte-stimulating hormone.

In urogenital sinus anomalies the location of the anus should be noted. Although it is usually in the normal location, anterior displacement is not uncommon, and this bridges the gap to cloacal anomalies (see Fig. 151-3). A gentle rectal examination is helpful in identifying a cervix.

Examination of a child with a persistent cloaca deserves special mention. There is a single perineal orifice because the rectum also enters this common channel. The appearance of the external genitalia assumes a much wider spectrum, from a nearly normal female appearance to much more bizarre appearances such as complete genital transposition or a blank-appearing (doll-like) perineum (Fig. 151-5) (Hendren, 1989). In some instances there is an enlarged phallic structure that gives the genitalia an ambiguous appearance. The single perineal opening may exit what appears to be a normal vaginal introitus, or it may extend to the tip of a phallic structure. I as well as others have encountered children with a secondary accessory channel that exits the tip of the phallus (Hendren, 1989; Karlin et al, 1989; Krstic et al, 2001; Rink et al, 2005b).

Cloacal anomalies are associated with a high incidence of related anomalies in other organ systems. I found 14 of 23 patients with renal anomalies, including 6 with solitary kidneys, 4 with renal dysplasia, 2 with ureteropelvic junction obstruction, 1 with duplication, and 1 with crossed fused ectopia; there were also 2 with bladder duplications (Rink et al, 2005b). Sixty percent have some degree of septation of the vagina and uterus (Warne et al, 2003). Kay and Tank (1977) reported that 13% of patients with cloacal anomalies have cardiovascular abnormalities, 10% have central nervous system problems, and respiratory abnormalities are noted in 5%; vertebral, particularly sacral, anomalies are common. Many have the VACTERL association (Vertebral abnormalities, Anal atresia, Cardiac abnormalities, Tracheoesophageal fistula and/or Esophageal atresia, Renal agenesis and dysplasia, and Limb defects), so tracheoesophageal fistula is often present (Hendren, 1986, 1988). Other gastrointestinal anomalies have been noted, including duodenal atresia and rectal duplication in 2% (Karlin et al, 1989).

Radiographic and Endoscopic Evaluation

Urogenital Sinus Abnormalities

Certain critical details of the anatomy, including the length of the common urogenital sinus, the location of the vaginal confluence and its proximity to the bladder neck, the size of the vagina and the number of vaginas, the presence of a cervix, and bladder and urethral anatomy, must be defined. This can be done radiographically or endoscopically. I believe that the location of the vagina in

KEY POINTS: UROGENITAL SINUS ANOMALIES—EVALUATION

- Key points of the history and physical examination are findings of a family history of sudden infant death, fluid and electrolyte abnormalities, hypertension, suprapubic mass, lower extremity cyanosis, palpable gonads, and hyperpigmentation, and number of perineal orifices.
- The level of the urethrovaginal confluence and the location of the rectum must be identified radiographically and endoscopically, with note made of their relationship to the bladder neck. Ultrasonography is mandatory to look for the uterus, ovaries, and kidneys.

relation to the bladder neck is the critical issue in determining the type of surgery, and this distance is far more important than the length of the common channel ([Rink et al, 2005a](#); [Ludwikowski and González, 2013](#)). Vaginal confluence with the urinary tract in pure urogenital sinus and cloacal anomalies occurs in a continuum from the bladder to a nearly normal location in the perineum. It is not simply “high” (proximal/suprasphincteric) or “low” (distal/infrasphincteric) ([Hendren and Crawford, 1969](#); [Powell et al, 1995](#); [Rink and Kaefer, 2002](#)) ([Fig. 151-6](#)). I am in agreement with [Ganesan and colleagues \(2002\)](#) that the confluence of the urethra and vagina in CAH is fairly constant with a normal proximal urethra. It is the distance from the vagina to the meatus that lengthens with increasing virilization, making some appear to be “very high.” Furthermore, this high confluence appearance is exacerbated in the more virilized urogenital sinus because there may be the appearance of a well-defined (male-like) external sphincter with a verumontanum appearance to the vaginal confluence just proximal to it and the bony pelvis is more masculinized.

A new urogenital sinus classification that measures the exact distance of the common channel and the distance of the bladder neck to the vagina has been devised to help delineate the exact level of the confluence, as well as clitoral size and appearance of the external genitalia ([Rink et al, 2005a](#)).

Ultrasonography of the urinary tract and pelvis is mandatory. The location and normalcy of the kidneys, ovaries, and uterus should be defined. Any bladder or vaginal distention should be

Figure 151-7. Genitography showing low confluence of the urethra and vagina.

noted. A cerebriiform appearance with enlargement of the adrenal glands is indicative of CAH ([Brock et al, 1998](#)).

Filling the entire bladder, urethra, vagina, and sinus with contrast (i.e., genitography) is critical in the anatomic evaluation of many children with a urogenital sinus ([Figs. 151-7 and 151-8](#)). Genitography is performed by placing a Foley catheter with the balloon occluding the perineal meatus and injecting a contrast agent. It is often helpful to pass a catheter into the bladder as for a voiding cystourethrogram. In some children, the vagina will only be demonstrated with voiding. A cervical impression at the vaginal dome denotes normal female internal organs. Magnetic resonance imaging (MRI) is of limited value in CAH but may be very helpful to define the anatomy in pure urogenital sinus anomalies or other DSD and cloacal conditions. In CAH patients, the internal anatomy can nearly always be defined by an endoscopy at the time

Figure 151-8. Genitography showing high confluence of the vagina entering near the bladder neck, with flow of contrast medium into the uterus.

of reconstruction, making genitography less useful in this group (VanderBrink et al, 2010). In our institution, the anatomy was accurately defined in CAH in only 72% of cases by genitography and it did not provide any information that could not be obtained by endoscopy, and genitography did not influence the type of timing of surgery (VanderBrink et al, 2010).

The most helpful diagnostic study in defining the anatomy for surgical reconstruction is endoscopy. In patients with CAH, endoscopy is usually performed at the time of reconstruction but may be necessary as a separate early procedure to help with gender identity in other DSD cases or in those with complex pure urogenital sinus anomalies or if the vagina is not identified on genitography (Rink and Kaefer, 2002). In the latter situation, multiple punctuate openings in the proximal portion of the urethra may be observed (Donahoe and Gustafson, 1994). I have found it helpful to pass a ureteral catheter into the opening and evaluate the vagina fluoroscopically in this situation (Rink and Kaefer, 2002). Again, the exact location, size, and number of the vaginas should be recorded (Fig. 151-9). Hendren has noted a male-like external sphincter in severely masculinized children, with the vagina entering proximal to it in a verumontanum-like structure (Hendren and Crawford, 1969; Hendren and Atala, 1995). In my initial experience, I thought this rarely if ever occurred (Adams and Rink, 1998), but as noted earlier, I have more recently seen several CAH children with a completely masculinized male-like urethra with an external sphincter and verumontanum-like structure.

Rarely, even with the evaluation described, some children with DSD require gonadal biopsy or evaluation of the internal genitalia, which has historically been done by laparotomy but in most cases can now be easily performed laparoscopically. Regardless of the means, it should be performed only when the findings would influence the gender of rearing (Rink and Adams, 1999). If a biopsy is

Figure 151-9. Endoscopic view of confluence. The urethra is superior; the vagina is inferior.

necessary, a deep incision should be made in the gonad because the ovarian component of ovotestes may completely surround the testicular component or be located at the poles (Hensle and Kennedy, 1998; Schnitzer and Donahoe, 2001). Finally, scrotal skin biopsy may at times be helpful in males with incomplete androgen insensitivity, decreased 5 α -reductase activity, or decreased dihydrotestosterone binding (Griffin and Wilson, 1989). Certainly all children with DSD should undergo chromosomal, endocrinologic, and genetic evaluation. This is well described in Chapter 150.

Cloacal Anomalies

Evaluation for cloacal anomalies begins with antenatal ultrasonography because several groups have now reported the prenatal diagnosis of persistent cloaca (Shalev et al, 1986; Petrikovsky et al, 1988; Cilento et al, 1994; Odibo et al, 1997; Adams and Rink, 1998; Cacciaguerra et al, 1998; Warne et al, 2002a). The diagnosis has been made as early as 19 weeks' gestation. The finding of transient fetal ascites with bilobed or trilobed pelvic cystic structures, bilateral hydronephrosis, and decreased amniotic fluid is diagnostic (Cacciaguerra et al, 1998; Warne et al, 2002b). The ascites is thought to develop via retrograde flow of urine into the uterus and out the fallopian tubes secondary to outlet obstruction from the distended vagina (Adams et al, 1998; Cacciaguerra et al, 1998).

Postnatal radiographic evaluation begins with a plain abdominal film (Jaramillo et al, 1990) and abdominal ultrasonography. A pelvic mass may be obvious on a kidneys, ureters, and bladder view. Retrograde flow of urine and meconium, as described earlier, may result in the classic linear calcifications or calcified meconium. More granular calcifications may be noted along the course of the rectum as a result of urine flow into the rectum that yields calcified meconium (Jaramillo et al, 1990). Abdominal ultrasonography is very important to visualize not only the pelvic anatomy but also the kidneys because hydronephrosis is common (Hendren, 1998). Hydronephrosis is usually related to hydrocolpos, with the distended vagina compressing the bladder neck and resulting in varying degrees of bladder outlet obstruction (Hendren, 1998). Ureteral compression may also occur; however, I have seen hydronephrosis caused by primary obstructive megaureter in patients with cloacal anomaly.

Figure 151-10. Pelvic ultrasonography in a patient with a cloaca. Duplicate fluid-filled vaginas are seen posterior to the decompressed bladder (B).

Ultrasonography may also detect other renal anomalies. Renal anomalies such as dysplasia, fusion anomalies, ectopia, uretero-pelvic junction obstruction, and duplication have been seen in 33% to 83% of children with a persistent cloaca (Kay and Tank, 1977; Warne et al, 2002a; Rink et al, 2005b).

As opposed to some urogenital sinus abnormalities in CAH in which genitography may be avoided, both genitography and endoscopy are mandatory to define the anatomy, which is even more complex with a cloacal anomaly.

The technique and goals of genitography and endoscopy are the same but must now include identification of the rectal as well as the vaginal confluence. The length of the urethra and its communication with the cloaca are important for reconstructive purposes. In Hendren's patients, the urinary communication to the cloaca was urethral in 77%, but in 23% there was virtually no urethra and the communication was noted at the bladder neck level (Jaramillo et al, 1990). The vaginal anatomy is also much more complex and variable. In Hendren's report of 154 patients, 66 had one vagina, 68 had two vaginas, and the vagina was absent in 20 (Hendren, 1998). Vaginal duplication has been seen in nearly all of my patient population (Rink and Yerkes, 2001) (Fig. 151-10). The duplication anatomy is also variable. Most authors have observed that the vaginas enter side by side with a single opening into the cloaca, but separate openings have been noted. The vaginas may be of different size, and one may enter the sidewall of the other. A cervix is usually seen at the top of each vagina. The vaginal entrance into the cloaca again lies along a spectrum from the bladder to a location near the perineum. Although the uterus is usually similar to the vagina (i.e., two vaginas with two uteri), the vagina may be absent with the uterus still present or the uterus may be hypoplastic. Hall and associates (1985) found a bicornuate uterus, hypoplastic uterus, or uterus didelphys in 35% of their patients with persistent cloaca.

The rectal confluence is equally complex, with the entrance in my experience most commonly located just at the level of the vaginal confluence. This rectal opening may be broad or it may have a long, narrow fistulous tract. It can even enter the vagina or bladder with no communication to the common cloaca itself. The most common entrance in my experience is within the septum of a duplicated vagina, with all three joining the cloaca together (Rink and Kaefer, 2002). The rectal communication has been found to be vaginal in 68% and cloacal in 11%, with the remainder in other locations (Jaramillo et al, 1990). The length and configuration of the common cloaca should also be noted because it has important surgical as well as anatomic implications. At times, the

common channel is narrow and appears very much like a urethra; in other instances, the channel is much larger and redundant and appears more like a vagina. The urethral appearance was found in 48% of patients and the vaginal appearance in 52% (Jaramillo et al, 1990). I and others have noted that the urethral types result in higher outlet resistance and are more likely to lead to hydrocolpos (Adams et al, 1998; Warne et al, 2002b).

The frequent presence of associated organ system abnormalities necessitates further radiographic evaluation. Echocardiography should always be performed. MRI is necessary for evaluating the lumbosacral spine and assessing the pelvic anatomy and musculature. Historically, it has been well recognized that sacral anomalies are common. Peña (1989) noted a normal sacrum in only 35% of his 54 patients, and Jaramillo and coworkers (1990) reported sacral agenesis in 40% of Hendren's 65 patients. De Filippo and associates (1999) found 10 of 21 patients with imperforate anus or cloaca to have an abnormality of the sacrum and spine. With the use of MRI, spinal cord abnormalities have been more commonly detected, with an incidence as high as 43% (Jaramillo et al, 1990). Hendren (1998) found that a third of his patients had a tethered spinal cord. Skin stigmata in the lumbosacral region were absent in 8 of 10 patients with spinal cord tethering in a report by Morimoto and colleagues (2003). MRI has also been very helpful in defining the level of the rectal atresia and in identifying the degree of sphincteric muscle development (Sato et al, 1988).

Because of the complexity of the anatomy and the frequency of hydrometrocolpos, a child with a cloacal anomaly often needs endoscopy early as a separate procedure to decompress the vagina and bladder and to define the anatomy. As a general rule, visualization of the vagina (or vaginas) is easily accomplished, but entry into the bladder can be very difficult and even impossible at times in a neonate because it is compressed very anteriorly by the distended vagina. The vagina should always first be emptied. Identification of the rectal fistula can also be difficult at times. Once it is located, mucus and fecal material should be irrigated from the colon, which can be done by irrigation through the scope in combination with irrigation through the mucous fistula of the divided colostomy. Passage of a small catheter through the mucous fistula when present can be very help in defining the location of the rectal confluence. The length of the urethra to the vaginal and rectal confluence as well as the length of the common cloacal channel should be documented. The length of the common channel is helpful in cloacal patients in predicting fecal continence outcomes (Peña et al, 2004).

SURGICAL RECONSTRUCTION OF DISORDERS OF SEX DEVELOPMENT AND UROGENITAL SINUS

Initial Management, Timing, and Principles

The majority of children born with a urogenital sinus have genital ambiguity, and this should be initially evaluated by the gender assignment team. It is extremely important that the family be made aware of all controversies surrounding genital surgery. Certainly, most families, physicians, and surgeons have historically made the decision to proceed with early feminizing procedures to "normalize" the child and allow a positive psychosocial adjustment (Schober, 1998). This has been thought to relieve the parents' distress and improve their outlook toward their child, although there is limited evidence for this. The thought has been that raising a child with genital ambiguity would be extremely difficult (Thomas, 2004). Creighton and colleagues (2012) have noted that the idea of "doing nothing" can be a stressful concept for the parents. Trakakis and associates (2009) stated that surgical treatment must be offered between 2 and 6 months because the tissues are maximally pliable and psychological trauma is minimized. Clearly, gender assignment when the individual's ultimate gender identity is unknown is a challenge and is at the core of this controversy (Mouriquand et al, 2014). A number of advocacy groups and physicians have begun to question the wisdom of early surgery. Informed

Figure 151-11. External appearance of genitalia in congenital adrenal hyperplasia. A, Moderately virilized with incomplete labioscrotal fusion. B, Moderately virilized with complete labioscrotal fusion. C, Severely virilized.

consent is impossible with an infant, and many believe that the decision for genital surgery is a right of the patient, not the parents. The ethical issues involving parents' rights and responsibilities to make decisions for their child remain unresolved (Lee and Witchel, 2002). Unfortunately, the infant is the passive center of the team but ultimately has the most important voice (Yerkes and Rink, 2010). In 2002, Rangecroft noted that data on the impact of raising a child with genital ambiguity are still lacking (Rangecroft, 2002). Regardless of one's personal beliefs, all pros and cons of both surgery and observation must be presented to the parents without bias, and certainly observation with psychological and peer support must be an option (Creighton and Liao, 2004). However, this same psychological and peer support should be given to the parents who do elect to proceed with early surgical management (Rink and Szymanski, 2015).

With current operative techniques, excellent cosmetic results can be achieved with feminizing genitoplasty for the virilized female. While anatomic appearance likely plays a role, it must be remembered that one's sexual identity is a result of many factors (Mouriquand et al, 2014). It is known that the brain is the dominant organ in sexual orientation (Woodhouse, 2004). Schober (1999) has pointed out that little is known about how adults adjust to genitoplasty, nor are there any data on what path infants undergoing genitoplasty might have chosen had the opportunity been given to them as adults. Feminizing genitoplasty is unique in that outcomes of early surgery are not known for perhaps 20 years and the results reported at this time may be based on techniques no longer used. However, it is clear that genital surgery does not "cure" a DSD. It is known that women with CAH are less satisfied with their genitalia than control subjects whether they had undergone an operation or not (Nordenskjöld et al, 2008).

Unfortunately, a dilemma remains for DSD surgery because there is no absolute correct answer at this time. Information should never be withheld from the parents. Secrecy from the family or patient has no place in the care of DSD. Counseling should be provided. Parents must be informed of all risks and options and be made aware of the current state of knowledge. They should also be given access to advocacy groups regardless of the group's stance on surgery. There is then a changing of attitudes toward early reconstructive procedures particularly with regard to clitoral surgery (Lee et al, 2006).

For the purposes of the remaining description of surgical techniques, it is assumed that all parties (parents and multidisciplinary team) agree that surgery is warranted.

Children born with a urogenital sinus associated with genital ambiguity usually have clitoral hypertrophy, some degree of fusion and anterior displacement of the labia majora with absence of the labia minora, and a common urogenital sinus (Fig. 151-11). Furthermore, it has been shown that there is significant variability in what is considered normal clitoral, vaginal, and labial size (Lloyd et al, 2005; Akbiyik and Kutlu, 2010). Genital reconstruction should address all of these issues and therefore generally involves three steps: (1) clitoroplasty, (2) labioplasty, and (3) vaginoplasty.

Historically, clitoroplasty has been performed early in life, but this has again been challenged by DSD advocacy groups and physicians. In the mid 1900s there was not thought to be an optimal timing for reconstruction (Jones and Jones, 1954; Lattimer, 1961), but more recently clitoral reconstruction has been carried out progressively earlier. Gross and colleagues (1966) and Spence and Allen (1973) noted that clitoral surgery can ideally be performed when the child is 1 year old. By the 1980s, clitoral surgery was recommended as early as the first few months of life (Snyder et al, 1983). More recently, de Jong and Boemers (1995) reported surgical correction at 1 to 3 weeks of age. Parents are now less likely to choose surgery for minimal clitoral hypertrophy (Lee and Witchel, 2002), and a consensus document recommends surgery for only the more severe degrees of hypertrophy (Prader III to IV) (Hughes et al, 2006). In a recent review on timing it was suggested that clitoral surgery be considered in infancy for Prader score of III or greater (Speiser et al, 2010). Most recent reports agree with early surgery for severe clitoral hypertrophy (Braga and Salle, 2009; Escala Aguirre et al, 2009; Speiser et al, 2010; Vidal et al, 2010; Acimi, 2013; Guarino et al, 2013; Willihnganz-Lawson et al, 2013). Johannsen and coworkers (2010) noted a higher satisfaction with clitoral function the younger the age at clitoral surgery.

The optimal timing for vaginoplasty continues to be debated. It is important to remember that the vagina serves no function in childhood. Some have based the timing partly on the level of the vaginal confluence. A consensus statement on CAH from the Lawson-Wilkins Pediatric Endocrine Society (LWPES) and the European Society for Pediatric Endocrinology (ESPE) recommends

surgery in the 2- to 6-month-old range for those with a high vaginal confluence, and surgery between 12 months and adolescence is not recommended (Joint LWPES/ESPE CAH Working Group, 2002). "There is inadequate evidence currently in relation to establishment of functional anatomy, to abandon the practice of early separation of the vagina and urethra" (Hughes et al, 2006). In a poll of delegates at the IVth World Congress of the International Society of Hypospadias and Disorders of Sex Development, surgery before 2 years of age was preferred by 78% of surgeons and most suggested single-stage clitoroplasty, vaginoplasty, and labioplasty (Yankovic et al, 2013).

Simultaneous performance of clitoroplasty, vaginoplasty, and labioplasty has been the standard practice for a child with a low (distal) vaginal confluence. Two separate schools of thought have been put forth for a high vaginal confluence. Some believe that the high rate of vaginal stenosis warrants delay of vaginal surgery until after puberty, which also avoids any need for vaginal dilation (Sotiropoulos et al, 1976; Snyder et al, 1983; Alizai et al, 1999; Creighton et al, 2001; Rangecroft, 2002; Thomas, 2004; Escala Aguirre et al, 2009). Others have recommended that vaginoplasty for the small hypoplastic vagina (<3 cm) be delayed also (Salle et al, 2012). Others have found the incidence of vaginal stenosis to be higher in those who undergo surgery after puberty rather than during infancy (Eroglu et al, 2004). I along with others believe that vaginoplasty, regardless of the vaginal location, is best combined with clitoroplasty and labioplasty in a single-stage procedure. This allows the surgeon flexibility in using redundant phallic skin for the reconstruction, which is compromised when the skin has previously been mobilized (Mandell et al, 1988; Gonzalez and Fernandes, 1990; de Jong and Boemers, 1995; Hendren and Atala, 1995; Rink et al, 1997; Passerini-Glazel, 1998; Vidal et al, 2010). Lean and colleagues (2007) found any plans for one-stage repair to give better results. Furthermore, several authors have noted that maternal estrogen stimulation of the child's genitalia results in thicker vaginal tissue that is better vascularized, thus making it easier to perform early vaginal mobilization (Passerini-Glazel, 1989; Donahoe and Gustafson, 1994; de Jong and Boemers, 1995; Rink and Adams, 1999; Farkas et al, 2001; Hamza et al, 2001; Hensle and Bingham, 2002; Eroglu et al, 2004; Braga and Salle, 2009). Those in favor of pubertal surgery generally perform it for the high vagina and note the advantage of the patient being able to provide consent (Escala Aguirre et al, 2009; Guarino et al, 2013). Furthermore, Schober (2004) has noted that estrogen has a beneficial effect on tissue healing that along with vaginal growth and distention may result in improved outcomes, making puberty the best opportunity for reconstruction. Still others believe that a hybrid of these two—clitoroplasty and labioplasty in infancy with vaginoplasty at puberty—is most appropriate, particularly in the setting of a high vaginal confluence (Creighton and Farhat, 2005; Escala Aguirre et al, 2009; Guarino et al, 2013). The surgery is not easier and there is no evidence that actual healing is better at puberty (Braga and Salle, 2009). At this time there is no universal agreement among those caring for DSD children on optimal timing for vaginoplasty, nor are there adequate data comparing early versus late surgery.

The clitoris is a sexual organ; therefore when performing clitoroplasty, every effort is made to not only provide excellent cosmesis but also retain normal clitoral innervation for optimal sexual gratification. Clitoral surgery has undergone significant evolution since Hugh Hampton Young's work in 1934 (Young, 1937). Initial efforts were primarily directed at not just amputating the clitoris but also completely excising all clitoral tissue to avoid any later painful erection (Jones and Jones, 1954; Gross et al, 1966; Hendren and Crawford, 1969). Clitoral amputation was based on reports by Hampson (1955) and by Money (1955), who noted that the clitoris was not necessary for normal sexual response. As recognition of the importance of the clitoris evolved, several ingenious clitoral recession techniques that preserved the innervation and all clitoral tissue were reported. Lattimer (1961) recessed the clitoris in subcutaneous fat and buried it beneath the skin. He also denuded the glans epithelium, which would not be recommended today.

Kaplan (1967) reported an interesting technique of splitting the two corpora apart and performing closure in a transverse Heineke-Mikulicz fashion. Randolph and Hung (1970) and also Pellerin (1965) buried the corpora beneath the pubis. Efforts to preserve the glans based on a flap were attempted as early as the 1930s by Young, but the glans sloughed (Young, 1937). Schmid (1961) was the first to report excising corporeal tissue yet preserving the neurovascular bundle with the glans intact. Kumar and coworkers (1974) later noted a similar technique proposed by Kiefer the same year. Spence and Allen (1973) excised all of the clitoral shaft but left the glans intact to survive from the attached ventral urethral plate, but this technique excised all of the neurovascular bundle. Virtually all techniques since have been based on Schmid's preservation of the neurovascular bundle (Shaw, 1977; Barrett and Gonzales, 1980; Glassberg and Laungani, 1981; Mollard et al, 1981; Rajfer et al, 1982). Although the glans often did well with these techniques, shrinkage and devascularization occurred at times. Kogan and associates (1983) reported subtunical excision of the erectile tissue by incising laterally through the Buck fascia to resect the erectile corpus cavernosa tissue. Clitoroplasty techniques exhibited only minor technical advances until the recent demonstration of the neurovascular anatomy of the clitoris by Baskin and coworkers (1999). This work suggests that a ventral, rather than lateral, incision would preserve not only the main dorsal neurovascular bundle but also the neural branches that fan out laterally (Fig. 151-12). Currently, much research is under way to further evaluate clitoral neuroanatomy, as well as develop techniques to evaluate sexual sensitivity. I believe that the Buck fascia with its neurovascular bundle and glans should always be preserved. Pippi Salle reported a technique whereby the corporeal bodies are mobilized and disassembled and then placed in the labial fat. This allows the option of later use for reconstruction of the phallus should the patient choose a male gender identity (Pippi Salle et al, 2007).

Vaginoplasty techniques have similarly evolved, with all repairs based on a few landmark reports. Almost every vaginal repair today uses a posteriorly based perineal flap proposed by Lattimer and originally described by Fortunoff and coworkers in 1964. This wide-based "Fortunoff flap" has been modified to a more omega-shaped flap that has resulted in improved cosmesis (Jenak et al, 2001; Freitas-Filho et al, 2003). In 1969, Hendren and Crawford reported a "pull-through" vaginoplasty for a high vaginal confluence. Their efforts to establish the location of the vaginal confluence as the determining factor for the type of vaginoplasty remain the basis for all vaginoplasties today. Vaginal reconstruction techniques now generally take the form of one of four types:

1. The "cut-back" vaginoplasty is rarely used today. I and most authors believe it is only appropriate for simple labial fusion. However, Escala Aguirre and colleagues (2009) recently reported its use in Prader I and II children.
2. The "flap" vaginoplasty is applicable to a low (distal) vaginal confluence. In this procedure, the posterior walls of the sinus and vagina are opened, but the anterior wall of the vagina is left intact. The posterior perineal flap fits into the opened vagina. This procedure does not change the level of confluence; it simply widely opens the introitus and urogenital sinus (Rink and Adams, 1998). Mild degrees of female hypospadias are common with this technique. I and others believe that a flap vaginoplasty should never be used for patients with a very high vaginal confluence because it may result in a short hypospadiac urethra, vaginal voiding, infections, and even incontinence (Hendren and Atala, 1995; Rink and Adams, 1999).
3. The pull-through vaginoplasty may be used for any level of confluence but is generally reserved for a very high confluence. In this procedure, the vagina is separated from the urogenital sinus, and the sinus is used to create a urethra. The mobilized vagina may reach the perineum, but in most cases skin flaps have been required.
4. Complete vaginal replacement can be achieved by several techniques, but this is used only for a rudimentary or absent vagina.

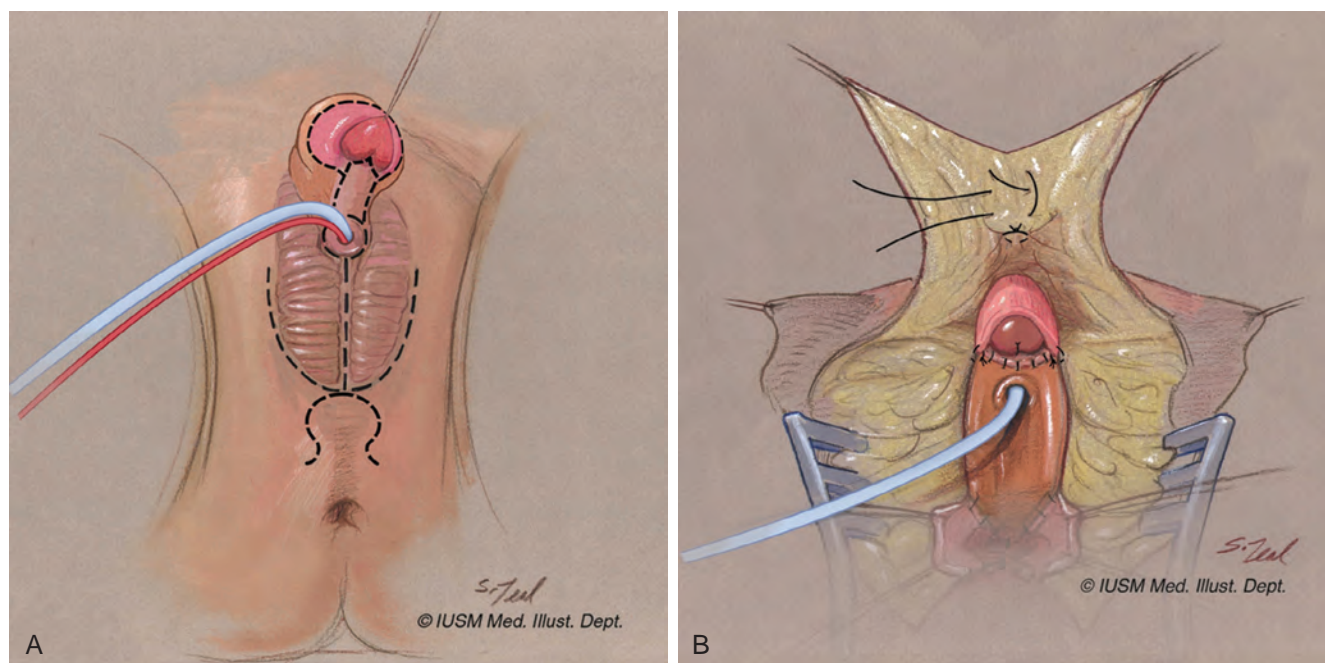

Figure 151-13. Labioplasty. A, Proposed incision lines for feminizing genitoplasty. Note preservation of skin cuff around glans clitoris that will be used to fashion clitoral hood. B, After recession of the glans clitoris the preputial skin is partially split to create the labia minora. The proximal preputial skin is plicated along its undersurface to create a "hooded" appearance to the segment of skin that will cover the glans. (© Indiana University Medical Illustration Department.)

Labioplasty techniques also continue to evolve. In CAH and other DSD states, the labia minora are absent and the labia majora are superior to the new vaginal introitus. Labia minora are created by using the split phallic skin as described by [Marberger \(1975\)](#). Both the labia majora and labia minora should be moved inferiorly by YV-plasty to create a normal cosmetic appearance of the vagina now located between the labia ([Hendren and Donahoe, 1980](#); [Rink and Adams, 1998](#)) ([Fig. 151-13](#)).

Regardless of the surgeon's personal bias toward reconstruction or its timing, a balanced presentation of all pros and cons of surgery versus no surgery is imperative. All current data should be made available to the parents and the risks associated with each

path clearly defined. The ultimate decision is the parents', but it should be made as a participant of a team. In the following sections, the techniques described are applicable to either infants or adolescents.

Current Operative Techniques for Female Disorders of Sex Development and Urogenital Sinus Repair

Preoperatively, it is important to ensure that the patient is metabolically stable, particularly a child with CAH. Most children with CAH only require an enema, but if there is an indication of a high

Figure 151-14. Total lower body preparation allows both supine (A) and prone (B) approaches.
(From Rink RC, Adams MC. Feminizing genitoplasty: state of the art. *World J Urol* 1998;16:212.)

confluence, complete bowel preparation with a polyethylene glycol-electrolyte solution (GoLYTELY) may be warranted. All children receive preoperative broad-spectrum antibiotics. Children with CAH must undergo “stress dose” steroid replacement at the time of surgery. After general anesthesia, endoscopy is performed as described previously. **After passing a Fogarty catheter into the vagina, the balloon is inflated and the catheter is clamped and left indwelling. A Foley catheter is then anchored in the bladder.** Both are kept sterile, and the child is prepared with povidone-iodine. Many surgeons prefer to place the child in lithotomy position, but I have found that this position limits vision to only the surgeon, hinders teaching, and does not allow manipulation of the child if a posterior or abdominal approach is unexpectedly needed. At the Riley Hospital for Children, all children undergo a complete lower body preparation from nipples to feet. The child’s legs are wrapped, and the lower part of the body is passed through the aperture in the drapes; this facilitates access to the entire perineum and abdomen and further allows the child to be rotated either supine or prone during the procedure (Fig. 151-14). In postpubertal patients such total body preparation may be difficult, necessitating the lithotomy position.

Low Vaginal Confluence: Clitoral Hypertrophy

The vast majority of children who undergo surgery for DSD or urogenital sinus conditions have a low vaginal confluence amenable to flap vaginoplasty. They usually have clitoral hypertrophy. Clitoroplasty and classic flap vaginoplasty are described. With the child in the supine position, a traction suture is placed through the glans and the proposed incisions are outlined with a skin scribe. Along these lines, 0.5% lidocaine with 1:200,000 epinephrine is injected subcutaneously for hemostasis. The proposed incision around the glans, leaving the inner surface of the prepuce intact, is drawn along with parallel longitudinal lines on either side of the ventral mucosal strip (urethral plate equivalent) extending around the meatus. A perineal omega-shaped flap with the apex near the meatus is outlined. A Y-shaped incision line is drawn around the inferior aspect of each labia majora. The incision begins on the dorsal aspect of the clitoris and all inner preputial skin is left intact for later construction of a clitoral hood. This skin has been shown to be second only to the glans in sensitivity (Schober and Ransley, 2002). The clitoris is degloved while keeping the ventral “urethral plate” intact with the meatus. Dissection is carried out to the level of the bifurcation of the corporeal bodies ventrally and the pubis dorsally, and care should be taken to not injure any neurovascular tissue (see Fig. 151-12). It is important to recognize that the clitoral arterial supply branches from the internal pudendal artery from the

KEY POINTS: UROGENITAL SINUS ANOMALIES—RECONSTRUCTION

- The three steps in surgical reconstruction are clitoroplasty, vaginoplasty, and labioplasty.
- Clitoroplasty is controversial. When performed, the glans and tunics with their neurovascular bundles must be preserved. Excision of erectile tissue, when performed, must be from the ventral aspect only.
- Vaginoplasties consist of four types: cut-back (generally no longer used), flap for a low to midlevel confluence, pull-through for a high confluence, and vaginal replacement for a rudimentary or absent vagina. The timing of vaginoplasties is controversial.
- Labia minora are absent in urogenital sinus patients with genital ambiguity. They are reconstructed from phallic skin. The anteriorly located labia majora should be moved inferiorly.
- It is helpful to place a Fogarty catheter with the balloon inflated in the vagina. For a low confluence, an omega-shaped perineal flap provides better cosmesis. The flap is sewn into the posteriorly opened sinus, and this flap must reach to the more proximal normal-caliber vagina.
- For a high confluence, the vagina may require separation from the urinary tract at its confluence and is “pulled through” toward the perineum. The sinus opening is closed to create a urethra. With a very small, very high confluence vagina the surgeon should strongly consider waiting until puberty for vaginoplasty.

Alcock canal near the ischial tuberosity. These arteries course ventrally and are on the medial aspect of the bifurcated corpora, where they then course dorsally along the phallic shaft (Schnitzer and Donahoe, 2001). The clitoral neural bundles ascend along the ischiopubic rami and meet as paired bundles that pass along the dorsal surface and then pass largely intact into the glans (Baskin et al, 1999; O’Connell et al, 2005). My current clitoroplasty technique is described but, regardless of technique, the just-described clitoral innervation must not be disturbed.

A tourniquet may be placed at the base of the clitoris or the bifurcated corpora may be compressed against the pubis with Kitner dissectors. Longitudinal incisions are then made through the Buck fascia on the ventralmost aspect of each corporeal body (Fig. 151-15); the incisions extend from the glans to the bifurcation to

Figure 151-15. Proposed clitoral incisions. Note the ventral location.
(© Indiana University Medical Illustration Department.)

expose the corpora cavernosa tissue, which is dissected (often teased) from the tunics. The tunics are left undisturbed, except for the ventral incision. **No tunical tissue is excised. The dorsal neurovascular bundle should not be mobilized or disturbed in any way.** The proximal ends of the erectile tissue only are suture ligated. Other techniques involve mobilization of the neurovascular bundles from the corpora, but I believe this is more likely to injure clitoral sensitivity and vascularity. If mobilization is done, [Braga and Salle \(2009\)](#) pointed out the need to dissect in the exact plane (below the second layer of the Buck fascia just beneath the tunica albuginea) to avoid neurovascular injury. Efforts to decrease the size of the glans are controversial and, if attempted, should be done with great caution. Studies by [Juskiewinski and associates \(1982\)](#) and [Baskin and colleagues \(1999\)](#) would suggest that any glans excision should be performed ventrally near the midline (similar to hypospadias glans wings). The glans is innervated by perforating branches entering at the dorsal junction of the glans and corpora ([Baskin et al, 1999](#)). Excision of glanular epithelium to conceal the glans is to be avoided because the sensory neuropeptides are located just beneath this layer. **Remember there are no data to suggest that a large glans is detrimental to sexual function.** The glans is now secured to the coronal stumps. In my experience, a glans sewn to the pubis results in an abnormally high prominent position ([Rink and Yerkes, 2001](#)). [Pippi Salle and associates \(2007\)](#) described an alternative technique whereby the corpora are dissected from the neurovascular bundle, separated, and buried beneath the labia, which allows reversibility of the clitoroplasty in those patients with later gender dysphoria.

With clitoroplasty completed, the flap vaginoplasty is started. The previously outlined omega-shaped flap is incised, and the underlying fat is mobilized with the flap to expose the urogenital sinus. The flap must be made long enough to provide a tension-free anastomosis to the vagina and wide enough to provide a normal-caliber introitus without compromising the blood supply of the perineal body. It should not be redundant because this will create an obstructing mound of tissue at the introitus. The posterior wall of the sinus and vagina is now dissected free from the underlying

rectum. This initial posterior step in separating the vagina from the rectum is the most difficult. With stay sutures in the meatus, the posterior wall of the sinus is opened in the midline and extended proximally into the posterior wall of the vagina. **The distal third of the vagina is usually narrowed; therefore the posterior wall incision must be carried proximally until normal-caliber vagina is encountered.** Sutures are placed individually through the perineal flap and then through the split posterior wall of the vagina and tied.

The mobilized phallic skin is unfurled and divided longitudinally in the midline while stopping well short of the base to allow a clitoral hood. This tissue at its base is incorporated with the preputial skin to create a clitoral hood. Labia minora are now created with this split preputial skin, which is moved inferiorly and anastomosed to the preserved ventral plate and the lateral vaginal wall. I have found that the inferior placement of these flaps along the side of the vagina often results in an M-shaped clitoral hood, which can be overcome by plicating the dermis of the new hood to give it a more normal inverted U shape. The proposed Y-shaped incisions are now made around the inferior aspect of each labia majora. The labia are mobilized and secured inferiorly alongside the vagina as a YV-plasty. The vaginal introitus should now reside between the labia minora and majora rather than appear as an isolated hole on the perineum.

High Vaginal Confluence: with or without Clitoral Hypertrophy

Most believe that complete separation of the vagina from the urogenital sinus with a pull-through vaginoplasty, as proposed by [Hendren and Crawford \(1969\)](#), is the best solution to a high vaginal confluence. [Braga and Salle \(2009\)](#) recommend it only when the urogenital sinus is longer than 3 cm. Fortunately, this complex situation is found in only about 5% of patients with CAH ([Dumanian and Donahoe, 1992](#)). This high confluence is more commonly seen in pure urogenital sinus abnormalities. As noted earlier, I agree with [Ganesan and colleagues \(2002\)](#) that in the urogenital sinus associated with CAH, the severely virilized child may appear to have a high vaginal confluence but it is the shared common portion of the sinus that lengthens and there is relatively minimal shortening of the urethra. It is this lengthened common sinus in combination with the appearance of a more male-like external sphincter that gives it a high confluence appearance ([Ganesan et al, 2002](#)). Although the concept of vaginal separation and pull-through vaginoplasty was a major advance, the operation as originally described frequently resulted in an isolated vaginal opening that appeared to be separate from the remainder of the genitalia, and a mucosal lining was lacking ([Passerini-Glazel, 1989](#)). It was also technically difficult because of poor vision at the critical points ([Rink et al, 1997](#)). Several authors have addressed these issues. [Passerini-Glazel \(1989\)](#) used the mobilized sinus by dividing it dorsally; when tubularized with the phallic skin and folded back toward the vagina, it would create a more normal cosmetic result and provide excellent coverage in the area of the vaginal separation while helping to prevent a urethrovaginal fistula. He later used this as a flap to form the anterior vaginal wall rather than completely tubularizing it ([Passerini-Glazel, 1994](#)). [Gonzalez and Fernandes \(1990\)](#) used the preputial skin to construct the vaginal vestibule and anterior wall.

The critical and most technically demanding aspect of a pull-through vaginoplasty is the separation of the anterior wall of the vagina from the urethra and bladder neck. There is no obvious plane of dissection, and great care must be taken to avoid injury to the urinary tract and its sphincteric mechanism. This area is also the most difficult to visualize, and poor exposure naturally leads to poor results, with the potential for a stricture, fistula, diverticulum, or retained distal vagina ([Rink and Adams, 1998](#)). Furthermore this is an area of significant nerve supply for the vagina and urethra. Most surgeons have positioned the patient in the supine or lithotomy position. Several authors have reported means of improving exposure for this critical area. [Passerini-Glazel \(1989, 1994\)](#)

mobilized the vagina transtrigonally in difficult cases but later reported that this approach is seldom necessary. Similarly, the anterior sagittal transanorectal approach or ASTRA (division of the anterior rectal wall) has provided excellent exposure for separation of the vagina and certainly should be considered for those patients with a very high vaginal confluence (Di Benedetto et al, 1997; Dòmini et al, 1997; Rossi et al, 1998; Salle et al, 2012). A diverting colostomy has not been necessary with the ASTRA technique. Hendren and Atala (1995) reported lateral mobilization of the rectum but later stopped because of the difficulty of this maneuver. Rink and colleagues (1997) reported a midline posterior prone approach with retraction but not division of the rectum that provides excellent exposure for critical aspects of the pull-through vaginoplasty and is described here.

Endoscopy with Fogarty and Foley catheter placement and total-body preparation are as described for a flap vaginoplasty. If the child has associated clitoral hypertrophy, the clitoroplasty is performed with the child supine as described earlier for a low confluence. The child is then rotated to the prone position. In a patient with a pure urogenital sinus, the procedure is started with the patient in the prone position. Although I have found this to be very beneficial to provide improved exposure, others have not found it necessary (Ludwikowski and González, 2013).

The perineal omega-shaped flap incision is made as previously described, and then the flap is retracted posteriorly, with dissection now carried out in the midline between the posterior wall of the sinus/vagina and rectum. As dissection proceeds proximally, the rectum is easily retracted with a small Deaver retractor (Fig. 151-16) to expose the entire urogenital sinus without the need to divide the rectum. The entire length of the sinus may be divided in the midline posteriorly to the normal caliber of the vagina. The Deaver retractor is now placed in the vagina and with upward retraction easily exposes the anterior wall of the vagina at its confluence with the sinus. This allows dissection of the vagina from the urethra under direct vision (Fig. 151-17). The tissues are quite thin in this area, and one should always err on the side of the vagina. More proximally, the dissection becomes easier. Excellent vision is also

provided for tubularization of the sinus to create a urethra, which is closed in two or three layers over a Foley catheter. The anterior wall of the vagina is now mobilized inferiorly, closer to the perineum. "Pull-through" vaginoplasty is often a misnomer because frequently the separated vagina will not reach the perineum. In this situation, skin flaps have been used to reach up to the vagina (rather than the vagina "pulled through" to the perineum). Preputial skin may be sewn to the spatulated anterior vagina, as described by Gonzalez and Fernandes (1990) or as modified by Acimi (2013) (Fig. 151-18). When preputial skin is not available, a buttock flap or a laterally based skin flap can be used (Parrott and Woodard, 1991; Dumanian and Donahoe, 1992; Moriya et al, 2009) (Fig. 151-19). The child is returned to the supine position, and the posterior perineal flap is anastomosed to the vagina as described for the flap vaginoplasty. I believe that skin flaps are best avoided because they are more likely to stenose and may be hair bearing. The use of urogenital tissue to create the flaps is more reliable, as in the Passerini-Glazel flap.

Labioplasty is now completed as described earlier. If a laterally based flap is required for the anterior wall, posterior relocation of the labia majora may be performed at a later stage.

In patients with a high confluence, particularly if multiple flaps have been used, the legs are bound together loosely postoperatively to prevent tension on the flaps. Although rarely required for urogenital sinus associated with CAH, the high confluence in the pure urogenital sinus patient may benefit from the ASTRA procedure noted earlier. In this procedure, with the patient prone, the posterior wall of the rectum is divided in the midline allowing excellent exposure of the high vagina for its separation and mobilization. This does not affect rectal continence and does not require a temporary colostomy.

Total and Partial Urogenital Mobilization

In 1997, Alberto Peña proposed a maneuver called *total urogenital mobilization (TUM)* as a means to complete the urogenital sinus component of a cloacal repair. In this procedure the entire sinus

Figure 151-16. A, Posterior flap developed with the sinus exposed. B, Sinus opened in the posterior midline. C, Retractor in the vagina. (© 1999, Indiana University Medical Illustration Department.)

Figure 151-17. A, Vagina mobilized and the sinus tubularized to create a urethra. B, Posterior vagina spatulated. (© 1999, Indiana University Medical Illustration Department.)

Figure 151-18. A and B, Modified Gonzalez preputial flap to create an anterior vaginal wall; the posterior flap has been anastomosed to the spatulated vagina. (© 1999, Indiana University Medical Illustration Department.)

is dissected circumferentially and mobilized toward the perineum. Peña noted a decrease in operative time by 70%, a superior cosmetic result, and less risk of fistula, vaginal stenosis, or acquired vaginal atresia with TUM because vaginal separation is not usually required (Peña, 1997). Since Peña's original description, TUM has been applied to several disorders, such as urogenital sinus, female exstrophy, and penile agenesis (Ludwikowski et al, 1999; Kropp and Cheng, 2000; Rink et al, 2006). Both Peña and Ludwikowski and

colleagues reported amputation of the mobilized sinus so that the vagina and urethra can be sewn flush to the perineum (Peña, 1997; Ludwikowski et al, 1999). I have reported using the mobilized sinus to provide a mucosa-lined vestibule or a Passerini flap to cover the anterior vaginal wall when a pull-through procedure is performed (Rink and Adams, 1999; Rink et al, 2006). Jenak and associates (2001) have since reported similar use of the mobilized sinus to create a mucosal vestibule, and Hamza and colleagues

Figure 151-19. A and B, A buttocks- or labial-based flap may be used to create the anterior vaginal wall in a patient with a pure urogenital sinus. (© 1999, Indiana University Medical Illustration Department.)

(2001) have noted that the sinus may be used as a Passerini-like flap. There have been two recent descriptions of use of the mobilized sinus to replace the posterior perineal-based skin flap with a sinus flap. In one, the sinus is split laterally and rotated posteriorly (Rink and Cain, 2002; Rink et al, 2006). In the other, the sinus is split in half longitudinally and the two halves are rotated inferiorly (Gosalbez et al, 2005). At the Riley Hospital for Children, I have incorporated urogenital mobilization techniques into nearly all of our urogenital sinus repairs. This allows a midlevel confluence to reach the perineum without requiring vaginal separation. The highest level confluences may still need a pull-through procedure with separation of the vagina and urethra, but it is much more easily performed after the urogenital sinus has been mobilized.

TUM is often thought of as its own type of vaginoplasty but is, in fact, a technique to allow vaginoplasty that may result in the vagina being sewn flush to the perineum; however, a flap or pull-through vaginoplasty may still be required. Only rarely do I believe the vagina should be sewn flush to the perineum, owing to concerns of a circumferential anastomosis becoming stenotic. TUM is started, as previously described, with endoscopy to evaluate the anatomy, to note the level of the confluence, and to place a Fogarty catheter in the vagina and a Foley catheter in the bladder. A sponge is placed in the rectum, and the proposed incisions are outlined. Subcutaneous injection of 0.5% lidocaine with 1 : 200,000 epinephrine along the lines is carried out. Clitoroplasty is performed as previously described, with the meatus of the urogenital sinus and urethral plate being circumscribed with stay sutures to allow mobilization of the sinus from the corporeal bodies. This is initially carried out to just between the bifurcation of the corporeal bodies. The clitoroplasty is now completed as described earlier. The dissection is carried out in the midline posterior to the sinus until the peritoneal reflection is reached to allow access to the entire posterior wall of the vagina (Figs. 151-20 and 151-21). This circumferential mobilization is done directly on the urogenital sinus and continues proximally beneath the pubis. As the avascular ligaments from the pubis to the sinus are divided in this area, the entire

Figure 151-20. Skin mobilized with the sinus exposed. (© 1999, Indiana University Medical Illustration Department.)

urogenital sinus is felt to “give” and move toward the perineum (Fig. 151-22).

The Fogarty balloon is now easily palpable in the vagina. The posterior wall of the vagina is opened between stay sutures. If the vagina is now near the perineum, it may be sewn flush to the

Figure 151-21. Total urogenital mobilization with the sinus mobilized. (© Indiana University Medical Illustration Department.)

Figure 151-22. Total urogenital mobilization. The sinus is mobilized to a position beneath the pubis. (© Indiana University Medical Illustration Department.)

perineum, or an omega-shaped perineal flap may be placed into the spatulated posterior wall to augment the vaginal caliber; I prefer the latter. Rather than discard the mobilized sinus, as previously reported, it is helpful to split the sinus ventrally and use it to provide a mucosa-lined vestibule (Fig. 151-23). If the vagina is still quite high, the anterior wall of the vagina should be separated from the urethra and bladder neck as in the pull-through procedure (Peña, 1997; Rink and Kaefer, 2002; Rink et al, 2006). This is most easily performed with the child in the prone position to allow direct vision. The opening in the urethra is closed in two layers. The mobilized sinus in this situation is split anteriorly and then used

Figure 151-23. A ventral incision on the mobilized sinus allows the creation of a mucosa-lined vestibule. (© Indiana University Medical Illustration Department.)

as a Passerini-like flap to create the anterior vagina wall (Rink and Adams, 1999; Rink et al, 2006) (Fig. 151-24). The posterior perineal flap is approximated to the spatulated posterior vaginal wall. Labioplasty is performed as previously described. TUM has achieved great popularity, and reports to date reveal excellent cosmesis and no problems with continence (Palmer et al, 2012; Ludwikowski and González, 2013). No long-term results are available.

Some have expressed concern regarding the proximal circumferential dissection because of the potential risk for sphincteric musculature or nerve injury. There is concern for resultant stress incontinence or foreshortening of the vagina. To address these concerns, Rink and associates (2005c, 2006) proposed *partial urogenital mobilization (PUM)*, a technique that starts with the same circumferential dissection but stops at the level of the pubourethral ligament (Fig. 151-25). This still allows use of the mobilized sinus as described earlier to improve cosmesis, yet it avoids the aggressive retropubic and suprapubic dissection and is applicable to the majority of patients. If more mobilization is necessary for a very high vagina, TUM is easily carried out.

KEY POINTS: UROGENITAL MOBILIZATION

- TUM is a technique applicable to both urogenital sinus and cloacal anomalies. The entire sinus is dissected circumferentially to above the pubis to allow the confluence to move inferiorly to the perineum.
- With the TUM or PUM technique, the mobilized sinus tissue can be used to create a mucosa-lined vestibule or an anterior or posterior vaginal wall. This sinus tissue should not be discarded.
- PUM circumferentially mobilizes the sinus to the level of the pubourethral ligament but does not extend above this level.

Results of Urogenital Sinus and Disorders of Sex Development Surgery

There are a number of significant issues when reviewing the data on surgery for DSD. The data are limited and nearly always

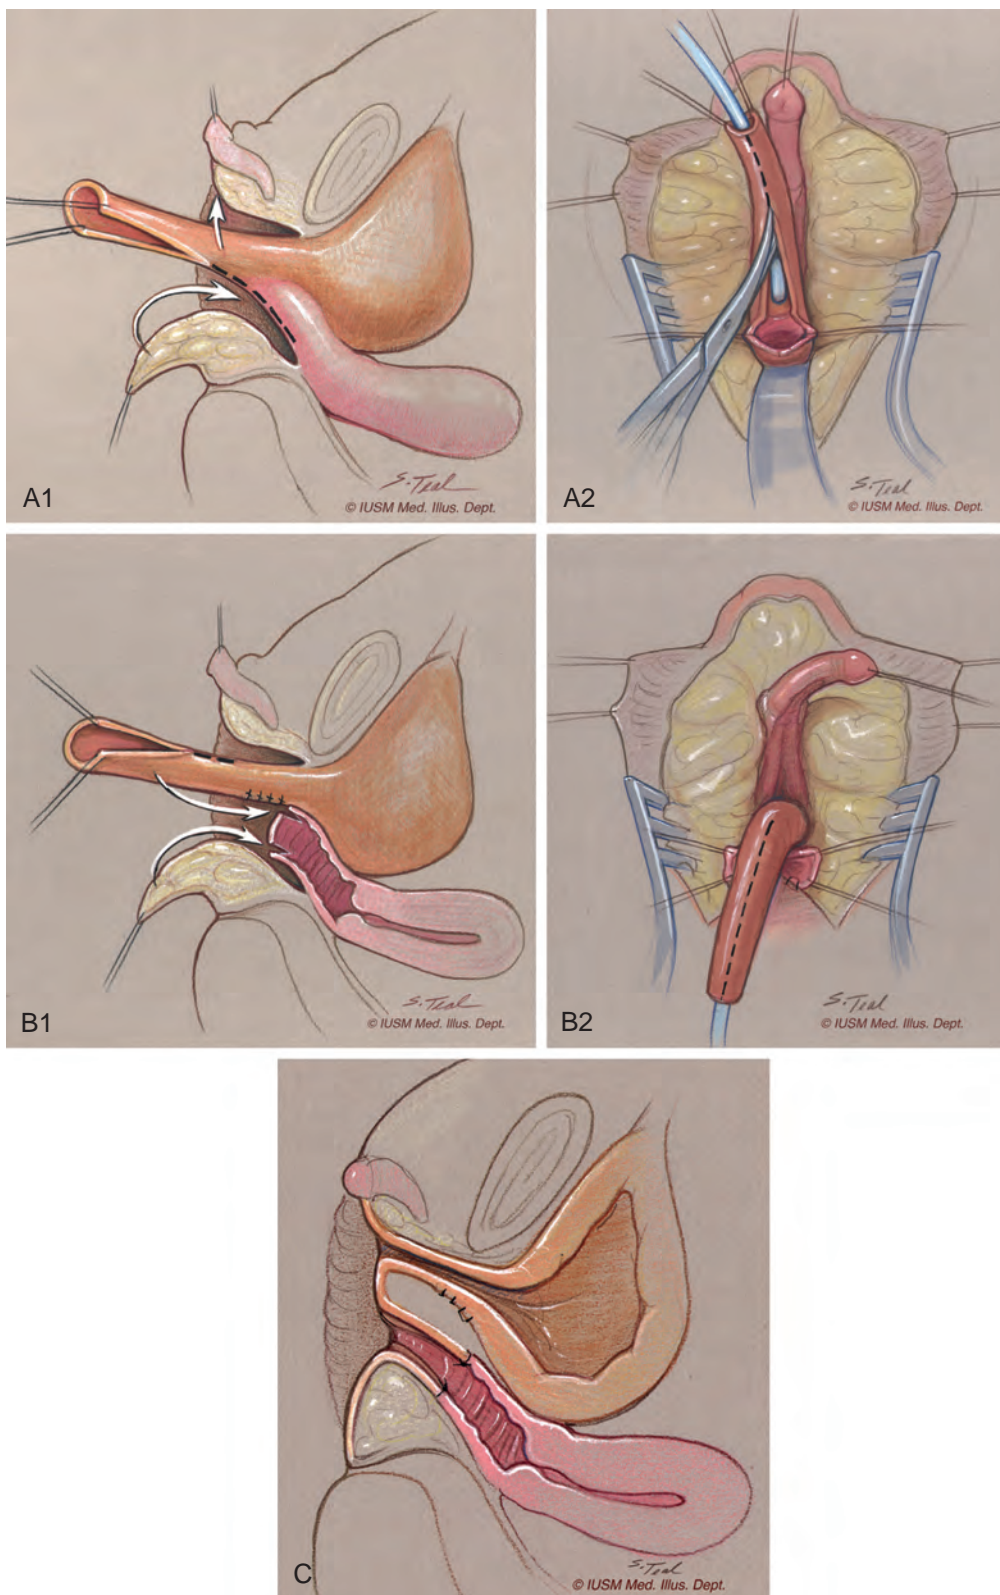

Figure 151-24. Total urogenital mobilization. A1 and A2, For flap vaginoplasty the sinus is split ventrally to create a mucosa-lined vestibule. B1 and B2, For pull-through vaginoplasty the sinus is split dorsally to create an anterior vaginal wall. C, The opened sinus now becomes the anterior vaginal wall. retrospective, reviewing only small numbers of patients, and the techniques reviewed are often outdated or not reported (Rink and Szymanski, 2015). Braga and Salle (2009) noted that available data were so poor that it was “scientifically pointless” to try to make sense of the current literature. Furthermore, most articles only look at success as an adequately open vagina with a feminized appearance. Success should include normal erotic sensation, lubrication, sexual satisfaction, orgasm, and intercourse without discomfort. These latter factors are just beginning to be studied. **Cosmetic and early functional results have uniformly been reported to be good. Long-term outcomes are of more concern.** Unfortunately in these studies it is often difficult to tell what procedures were done for what degree of severity of urogenital sinus, and none of the studies include data on the quality of endocrinologic control in these patients. Looking at what data are available, Jones and colleagues (1976) noted that 25 of 84 patients undergoing vaginoplasty required a secondary procedure to provide a vaginal outlet satisfactory for intercourse; 5 of these 25 also required a third procedure. **The poor results were caused by failure to exteriorize the vagina initially or by scar formation. The distal vagina is always narrow. The normal-caliber vagina must always be reached and exteriorized with current procedures.** Sotiropoulos and associates (1976) found that all patients undergoing prepubertal vaginoplasty required revision at puberty. Azziz and coworkers (1986) reported the results of attempted coitus in 42 women with CAH 23.6 years after vagina repair. Satisfactory coitus was noted in 62% (46% in salt wasters and 87% in those with the non-salt-losing form). There was a less favorable outcome when the initial procedure was performed before 1 year of age. Thirty secondary or tertiary procedures were needed to achieve the final results. These data are widely quoted, but almost all of these patients initially underwent a cut-back vaginoplasty (“incision of the urogenital sinus”), which is a procedure no longer used because it does not adequately open the vagina to the proximal normal caliber; specifically, the distal end of the vagina is narrowed and thus will be stenotic. Revisions for these patients involved the performance of a flap vaginoplasty, which currently would probably have been the initial procedure. In a series from Johns Hopkins Hospital, 28 patients (32% lost to follow-up) had adequate follow-up, 22 (78.6%) of whom needed further vaginal surgery (Bailez et al, 1992). Bailez and colleagues noted that if secondary surgery was needed for vaginal stenosis, success rates were high when the procedure was performed near puberty, with only 8 of 18 needing a secondary procedure requiring a flap. This

group also reported less favorable results in those younger than 1 year of age (Bailez et al, 1992). Nihoul-Fekete and colleagues (1982) noted that 30% of 43 CAH patients required secondary surgery. Hendren and Atala (1995), reporting on 16 patients with high vaginal confluence, noted that 6 of 9 adults had satisfactory coitus and 2 had vaginal stenosis.

Fourteen girls with CAH, 11 to 15 years old, who had undergone genitoplasty at a mean age of 2.5 years were assessed under anesthesia by Alizai and colleagues (1999), who noted that 13 of the 14 required additional vaginal surgery. Stenosis was seen in 43% and persistent urogenital sinus with or without fibrosis in 50%. Minto and coworkers (2003) found that 39% of 28 patients required secondary surgery and a third procedure was required in 11%. Al-Bassam and Gado (2004) noted vaginal stenosis in 16% of their patients who underwent various types of vaginoplasties (43 vaginoplasties: 26 flap, 11 pull-through, 2 cut-back, 3 sigmoid vaginal replacement). Nearly all underwent vaginal dilation. Vaginal stenosis was noted in 37% of Nordenskjöld and colleagues’ (2008) operated CAH patients, with 15 of 50 noting painful intercourse. However 24 of the 41 vaginoplasties were cut-backs, with 10 flaps and 7 combinations. In a cross-sectional study of Dutch women older than 15 years, 7 of 13 “single-stage” repairs required secondary surgery and of 20 women who had intercourse 8 complained of dyspareunia but only 2 had vaginal stenosis (van der Zwan et al, 2013). It is tempting to assume that postpubertal vaginal surgery may result in better outcomes, but there are no data to support this assumption. Furthermore Eroglu and associates (2004) actually noted less vaginal stenosis in those patients who underwent early single-stage repair (3.4%) than in those who underwent late vaginoplasty (42.8%). Lean and coworkers (2007) noted no difference whether the surgery was done before or after 2 years of age. In their series of 32 patients they noted good cosmesis in 72%, satisfactory in 22%, and poor in 6%. They believed that the planned one-stage operation gave better results than the planned multistage procedure, with only 2 of the 32 former patients requiring further major surgery and 3 needing minor revisions. Al-Bassam and Gado (2004) also recommended a single-stage repair at 3 to 6 months of age. It may be that the level of vaginal confluence and number of procedures is far more predictive of outcome than is the timing (van der Zwan et al, 2013).

It seems clear that a “single-stage” early vaginoplasty will probably require a secondary repair after puberty, but this should be expected because the orifice is likely to remain the size that was created given that there is no flow through the orifice in childhood. In my experience the secondary refinements are easily performed.

Surgical techniques to reduce clitoral size have dramatically improved and are now based on our current knowledge of clitoral neuroanatomy. Even though no long-term results are available for current techniques, some long-term results are now being reported for relatively modern techniques. Alizai and colleagues (1999) found clitoroplasty results to be unsatisfactory in 46% of the patients they assessed. Gearhart and coworkers (1995) looked at pudendal evoked potentials after clitoroplasty and noted that modern clitoroplasties preserve nerve conduction in the dorsal neurovascular bundle. Barrett and Gonzales (1980) found intact sensation in all of their patients after clitoroplasty. Chase (1996) reported that even with normal evoked potentials there may be an absence of sensation and orgasm. I have not noted vascularization defects after modern clitoroplasty. It is clear that further long-term studies are necessary. Minto and coworkers (2003) found the clitoris to be cosmetically normal in 59% of patients who had undergone clitoral surgery, but it was excessive in 20%, large in 7%, small in 7%, and absent in 7%. This group also reported that hot, cold, and vibratory sensation was markedly altered as recorded by a genitosensory analyzer. Sensation alone may be a poor indication of clitoral normality after surgery. Further studies to analyze the newest techniques are warranted. The erotic sensitivity and potential for orgasm should be studied. More recently, Nordenskjöld and colleagues (2008) compared 62 CAH patients with 62 controls. Of the 49 who underwent clitoroplasty, 16 had 1 operation, 14 had 2, 4 had 3, 4 had 4, and 11 had between 5 and 10 operative

procedures. Twenty percent were not satisfied with their surgery; they thought there was decreased sensitivity. However, 50% of the nonoperated patients thought their clitoris was too large. There was no difference in the ability to achieve orgasm between the two groups. The authors noted that women with CAH were less satisfied with their genitalia whether operated or not. [Nordenström and associates \(2010\)](#) noted that clitoral sensitivity was affected in nearly all patients who had undergone clitoroplasty. However, those with partial clitoral resection sparing more nerve function had a more favorable outcome and did not differ from those with no surgery. Initial degree of virilization also affected clitoral sensitivity.

The results of TUM and PUM are very early. These procedures are technically easier and the cosmetic results are superior, but whether the functional results are better is unknown. The potential for stress incontinence or denervation of the sphincteric mechanisms also is unknown. Most authors to date have not found continence to be altered by TUM ([Rink and Adams, 1999](#); [Hamza et al, 2001](#); [Kryger and Gonzales, 2004](#); [Rink et al, 2007](#); [Palmer et al, 2012](#); [Ludwikowski and González, 2013](#)). Until these results are available, these procedures should be used with caution.

Recently there has been effort to understand sexual function and mental health following feminizing genitoplasty. [Fagerholm and colleagues \(2012\)](#) noted that quality of life and health-related quality of life studies appeared normal in most patients and that mental health was similar to or better than published data from Finland. There were 5 of 24 patients who had some poorer scores because of distressful memories of too-late surgery, the operative treatment itself, or poor sexual function. This same group also noted that intercoital relationships started later in females who underwent genital reconstruction in childhood as compared to the normal population. In addition, the patients preferred surgery to be done early in life ([Fagerholm et al, 2012](#)). In a study of 62 Swedish women with CAH, [Nordenström and coworkers \(2010\)](#) reported several interesting results. Overall satisfaction with sexual function after feminizing genitoplasty was as good as controls except for the null genotype (salt-wasting CAH, most severely affected) CAH patients. The cosmetic score did not differ between those who were satisfied and those who were not, and cosmetic outcome did not contribute to sexual orientation. In this study, as in the study by [Wisniewski and colleagues \(2004\)](#), the physicians perceived the genital appearance as better than did the patients. [Callens and associates \(2012\)](#) noted that feminizing surgery did not seem to improve or hamper psychosexual outcome, especially in those patients with severe virilization.

There has been some concern that lower urinary tract symptoms are more likely in those patients with CAH ([Davies et al, 2005](#)) but in the recent study by [Fagerholm and colleagues \(2013\)](#) symptoms did not seem to differ in female DSD patients versus controls. Occasional lower urinary tract symptoms were common in both patients and controls ([Fagerholm et al, 2013](#)).

Timing of vaginoplasty remains quite controversial. Although the few reported long-term studies suggest that delayed vaginoplasty may be preferable, most surgeons continue to recommend early surgery, particularly for the CAH group ([Rink and Whittam, 2014](#); [Yankovic et al, 2013](#)). Most would recommend delaying vaginoplasty for the patient with a small, very high confluence vagina. They argue that the available long-term studies are based on outdated techniques and that there are tremendous surgical advantages to a single-stage repair. Supporters of early vaginoplasty well recognize that secondary introitoplasty may be necessary, but this is usually accomplished easily. The argument, which will not be settled soon, contrasts two approaches, both of which usually result in two procedures: (1) a simple procedure in an infant (i.e., clitorolabioplasty) with a postpubertal extensive procedure (i.e., vaginoplasty) or (2) an extensive single-stage clitorolabiovaginoplasty in an infant with a simple introitoplasty in the postpubertal period. There is also controversy on the correct timing to share information with the affected child. Unfortunately research on when to convey information is virtually nonexistent ([Sandberg et al, 2012](#)).

Several studies have noted that the most important factor affecting results is whether there was a surgeon or surgical team with a special interest in feminizing genitoplasty procedures ([Creighton et al, 2001](#); [Lean et al, 2007](#); [Nordenskjöld et al, 2008](#)). This suggests that support for Centers of Excellence may be appropriate for the care of children with DSD.

KEY POINTS: UROGENITAL SINUS ANOMALIES—OUTCOMES OF RECONSTRUCTION

- It is clear that neonatal vaginoplasties will usually require a secondary procedure for stenosis after puberty (25% to 100%).
- Successful coitus is often reported, but further studies should note sexual satisfaction, lubrication, and erotic sensitivity, as well as nonpainful coitus.
- Current techniques of clitoroplasty seem unlikely to injure sensation, but newer studies question whether sensitivity is an adequate indication of clitoral function. Some studies note decreased sensation with newer techniques.

SURGICAL RECONSTRUCTION FOR CLOACAL MALFORMATIONS

Initial Management, Timing, and Principles

The initial management of cloacal anomaly involves stabilization because the child is often quite ill with abdominal distention that at times results in respiratory compromise. As with all other anomalies, its management has evolved. Historically, after decompression of the distended organs it was common practice to perform a rectal pull-through procedure; genitourinary reconstruction followed at a later date, if at all ([Okonkwo and Crocker, 1977](#)). [Hall and coworkers \(1985\)](#) suggested that the vaginal surgery be done after puberty, when estrogen levels are higher. Although it is tempting to perform a pull-through procedure only, it is now clear that this piecemeal repair of the cloaca is a disservice to the child and is absolutely contraindicated. It is optimal to repair all abnormalities (i.e., rectal, vaginal, and urethral) in a single stage ([Kay and Tank, 1977](#); [Mollitt et al, 1981](#)). This allows the best exposure for the difficult rectal and vaginal separation. Furthermore, the tissues have not been previously violated, and the rectum does not require remobilization. [Hendren \(1982, 1986\)](#) pointed out that rectal pull-through should never be done as a separate procedure. Of his 154 patients with cloacal anomaly, 60 were secondary cases, many of whom had undergone a previous pull-through procedure. Definitive repair in this situation often requires repeat rectal mobilization. [Raffensperger \(1988\)](#) proposed neonatal complete repair but later noted that this may not be appropriate. [Levitt and Peña \(2005\)](#) have stated that there are three pitfalls in the management of neonates with cloacae: (1) failure to recognize and manage hydrocolpos, (2) colostomy or vesicostomy problems, and (3) clinical misdiagnosis.

Surgical management now involves four basic steps: (1) decompression of the gastrointestinal tract, (2) decompression of the genitourinary tract, (3) correction of nephron-destructive or potentially lethal urinary anomalies, and (4) definitive repair of the cloaca.

Decompression of the Gastrointestinal Tract

Decompression of the gastrointestinal tract is done by colostomy. Although nearly all surgeons agree on the need for colostomy initially, the best anatomic location of the colostomy is debated. Hendren initially recommended a low-loop colostomy but more recently has performed a right transverse colon divided colostomy ([Hendren, 1982, 1986, 1998](#)). This change was prompted by

difficulty in obtaining a bowel segment for vaginoplasty during the rectal pull-through procedure when a low colostomy has been performed. A divided transverse colostomy keeps the left colic blood supply intact (Hendren, 1992). Peña, as cited by Spitz and Coran (2006), preferred a descending colostomy because there was less surface area for resorption of urine. A divided colostomy in the descending colon just after the colon takes off from its retroperitoneal attachment is now recommended by Levitt and Peña (2005). This procedure maintains the availability of enough distal colon for future pull-through, and prolapse is less likely to occur. However, Peña did recommend leaving a long segment of sigmoid to prevent a difficult pull-through requiring abdominal exploration. Levitt and Peña (2005) noted that 24 of 361 patients had a colostomy too low that interfered with the rectal pull-through. I have favored a proximal colostomy but have at times found clinically challenging acidosis caused by urine absorption through the colonic mucosa. Masuko and associates (2005) reported successful decompression of the colon by balloon catheter drainage with irrigation of the bowel three times a day. This avoided temporary colostomy and allowed a single-stage repair.

At the time of colostomy, endoscopy may be performed to more clearly define the anatomy and to aid in decompression of the urinary tract. In my experience, as the cystoscope advances proximally through the cloacal channel, it tends to enter the vagina (or vaginas). In fact, entrance into the urethra/bladder can be extremely difficult in a neonate with a distended vagina because the vagina compressed the bladder to the anterior abdominal wall and obstructs the bladder neck. Drainage plus irrigation of the vagina (or vaginas) not only allows decompression and relief of abdominal distention but also may allow visualization of the bladder. Often, the rectal fistula is also difficult to locate; as noted previously, it is more often found within the septum of the duplicated vaginas but can enter at almost any location. With a combination of irrigation through the fistula and through the distal limb of the colostomy, the inspissated mucus and meconium can easily be cleared. It is often helpful to leave small feeding tubes in all channels and then obtain radiographic studies to further delineate the anatomy. In my experience this is best done in the radiology suite with fluoroscopy.

Decompression of the Genitourinary Tract

Even after decompression of all structures draining into the cloaca, at times voiding continues into the vagina (or vaginas) or the rectum (or both) and results in rapid distention of these structures with subsequent poor urinary drainage, persistent hydronephrosis, abdominal distention, urinary infection, and hyperchloremic acidosis. This can generally be managed by intermittent catheterization. The catheter often enters the vagina rather than the bladder, but it still functions to drain and decompress the genitourinary tract (Hendren, 1992). If the desired decompression is not achieved, further maneuvers are required. I agree with Hendren that, in a long urethra-like cloaca, catheterization can at times be difficult and a cut-back procedure (opening the cloaca) may be helpful to aid catheterization (Fig. 151-26). If this approach fails, further decompression can be achieved by either vesicostomy or vaginostomy (Kay and Tank, 1977). Levitt and Peña (2005, 2010) have found vaginostomy or tube vaginostomy to be helpful, but it is my belief that clean intermittent catheterization (CIC) should be the first-line treatment because it will usually keep the vagina adequately decompressed. Only when CIC fails should vesicostomy or vaginostomy be performed. The concern of tethering the vagina to the abdominal wall with later difficulty doing a pull-through or TUM has led some to recommend vesicostomy over vaginostomy but others have found this not to be a concern. It also necessitates an abdominal procedure. Levitt and Peña (2005) found that 25% of their cloaca patients had hydrocolpos but that in 59% of them it was either not identified or mismanaged. This resulted in significant morbidity from ureteral obstruction, urinary tract infection, acidosis, and failure to thrive. Adequate vaginal drainage resulted in resolution of these problems.

Figure 151-26. The urethra-like cloaca is opened, with a catheter in place; vesicostomy has also been performed.

Repair of Obstructive Urinary and Other Pathology

The third stage of care of a child with a cloacal anomaly is repair of any obstructive urinary tract pathologic process. Renal structural abnormalities, some of which were obstructive, have been identified in 60% to 83% of patients with persistent cloaca (Warne et al, 2003; Rink et al, 2005b). In those patients with a common channel longer than 3 cm, 91% had urologic defects (Peña et al, 2004). At times these anomalies are ignored early on while awaiting definitive cloacal repair, but this practice should be avoided. Obstructive lesions should be treated promptly. However, vesicoureteral reflux, which is quite common, can generally be managed medically if urinary infection is prevented. Other organ system anomalies (e.g., cardiac, spinal cord) should be fully evaluated. Some may require repair during this phase.

Definitive Repair of Cloacal Malformations

Definitive repair of a cloaca is usually carried out at 6 to 12 months of age, but obviously the child must be well nourished and thriving to proceed with repair. In healthy thriving children, Peña and colleagues (2004) operate at 1 month of age. Definitive repair should never occur until the urinary tract has been evaluated and hydrocolpos has been ruled out. If endoscopy has not been performed previously, it may be helpful as a separate procedure before the definitive repair. Defining the anatomy can be tedious, and it is helpful to thoroughly cleanse the distal colonic segment, which usually requires irrigation from the mucous fistula, as well as the distal limb of the colostomy. A standard Golytely bowel preparation should also be done.

Operative Technique: Cloaca

The definitive repair begins with endoscopy to reacquaint the surgeon with the anatomy. I have also found it is helpful to place

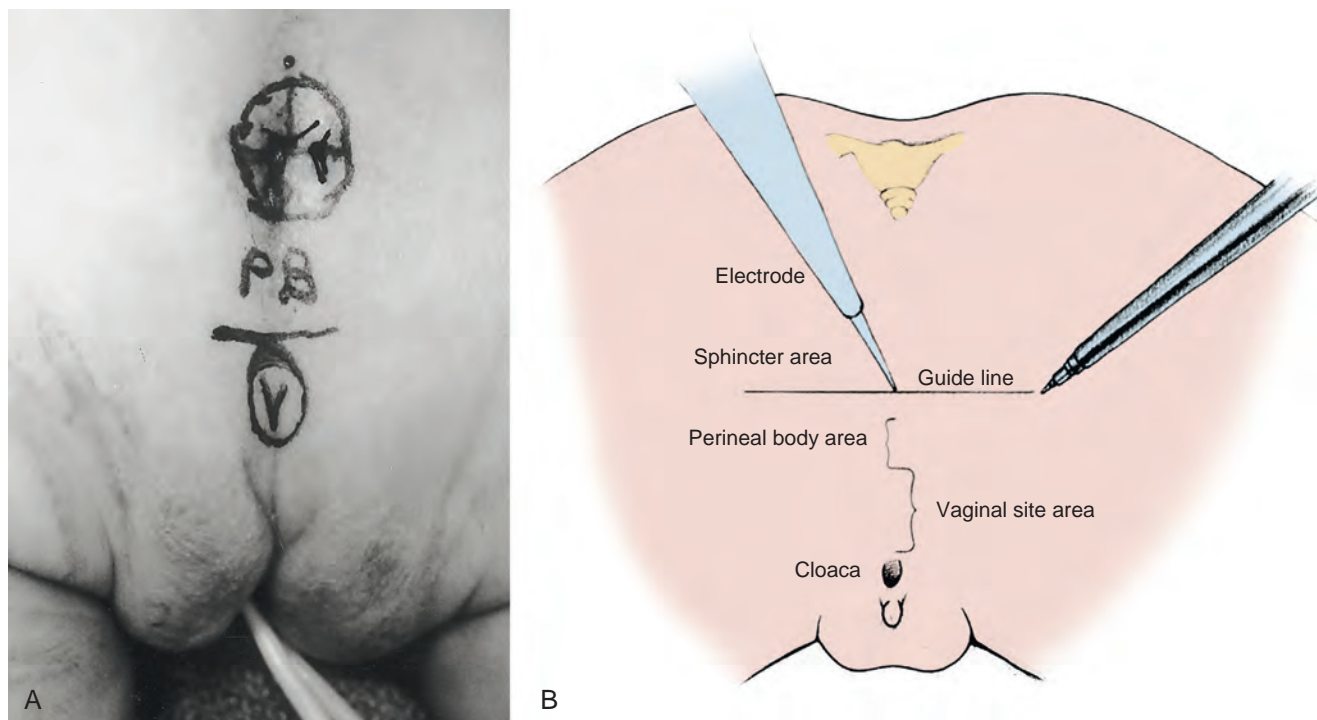

Figure 151-27. A, Cloaca: proposed location of the vagina (V) and perineal body (PB). B, Rectal location is identified by electrical stimulation.

a Foley catheter in the bladder and different-colored Fogarty catheters in the vagina (or vaginas) and rectum. The catheters are kept sterile during preparation. As described previously for urogenital sinus repair, a complete lower body preparation with povidone-iodine is done circumferentially from the level of the nipples to the toes, and the legs are wrapped sterily. Such preparation allows prone and supine positioning for perineal and abdominal surgery.

The definitive posterior sagittal anorectovaginourethroplasty (PSARVUP) is begun with the child in the prone position and the pelvis elevated on rolls to achieve a jackknife position. An electrical stimulator is used to determine the area of maximal contraction, which is marked with a skin scribe and with stay sutures for later rectal placement. The proposed locations of the perineal body and vagina are also marked (Fig. 151-27). I agree with Hendren (1992) that it is at times helpful to have a sound in the common cloacal channel, but the Foley and Fogarty catheters usually suffice. The entire dissection is done in the midline until mobilization of the rectum and vagina is begun. The most important advances of Peña's PSARVUP procedure are that it allows identification of the external sphincter and muscle complex of the rectum and provides excellent exposure for separation of the rectum and vagina (or vaginas) from the cloaca.

The initial incision extends from the tip of the coccyx in the midline to the posterior aspect of the cloacal orifice. Sutures mark the sphincteric muscular structures on either side as they are encountered. I have found it helpful in the past to open the common cloaca in the midline posteriorly to the level of the confluences to allow easy identification of the rectal and vaginal insertions. With TUM, this is less appropriate because it may limit the options for use of the sinus in the reconstruction as previously described for a urogenital sinus. When the rectal fistula is identified, it is opened posteriorly and multiple silk stay sutures are placed. These sutures are helpful in mobilizing the rectum away from the vagina (or vaginas). It is important to remember that the structures share a common wall initially and it is better to enter the vagina than either the rectum or urethra. Circumferential dissection of the rectum to well above the sacrum may be necessary. Separation of the peritoneum can be done from this position. Rarely, a child with a very

high rectal confluence needs to be turned to the supine position for abdominal exploration to free the rectum more proximally. Levitt and Peña (2010) have noted abdominal surgery to be more likely when the common channel is greater than 3 cm in length. Once adequate rectal mobilization to allow a tension-free anastomosis to the perineal skin has been achieved, the rectal stay sutures are used to retract the rectum from the genitourinary structures.

In the classic PSARVUP procedure, the vagina is now separated from the sinus. This dissection is even more tedious and difficult than the rectal separation. With TUM (described later), which has now achieved widespread acceptance for cloacal repair, the vagina may not require separation. In classic vaginal separation, as noted earlier, it is an error to enter the urinary tract during vaginal mobilization. Side-by-side vaginal duplication is most common, and the midline septum has been incised with electrocautery during the initial endoscopy. Hendren (1998) noted that 66 patients had a single vagina, 68 had two, and 20 had none. The Fogarty catheter (or catheters) within the vagina is easily palpable, and the posterior aspect of the vagina is opened at the level of the confluence. Again, circumferential stay sutures are very helpful in separating the vagina from the urethra and bladder. A malleable retractor inserted into the opened posterior vaginal wall exposes the anterior wall confluence for separation. Sharp dissection is less likely to injure the urinary tract than is cautery. Making dissection even more difficult is the realization that frequently the vagina almost encircles the urethra. Failure to recognize this situation can result in injury to these structures. Use of the stay suture for traction aids in further mobilization of the vagina (or vaginas). The outer wall of the vagina appears white, and identification of this color is helpful. Great care should be taken to avoid devascularization of the vagina during mobilization. Usually, vaginal mobilization allows the vagina to be "pulled through" to a position near the perineum. If after significant mobilization it still does not reach the perineum, skin flaps can be used to reach the spatulated vagina. With an extremely high vagina or the rare vaginal agenesis, it may be necessary to interpose a bowel segment to reach the perineum, which obviously requires abdominal surgery. With a very dilated vagina, a vaginal flap or vaginal "switch" can be created to reach the perineum, although care must

be taken to avoid devascularization and stenosis (Hendren, 1986; Peña, 1989; Peña et al, 2004).

Before the vagina is brought to the perineum, the openings in the common cloacal channel should be closed in two to three layers with absorbable suture to create a urethra. If the cloaca is large and resembles a vagina, it needs to be opened in its entirety and tailored over the Foley catheter. The vagina is then secured to the perineum. If there is any concern about vaginal injury, the vagina should be rotated to avoid overlapping suture lines (Hendren, 1992). The Foley catheter is left indwelling for 2 weeks.

Some surgeons have more recently noted that laparoscopic-assisted PSARVUP can help in achieving a low dissection of the fistula and accurate placements of the rectal pull-through, while allowing excellent visualization of the pelvic structures (Tei et al, 2003).

The perineal body is now reconstructed, and the rectum is pulled through to the perineum. Peña (1989) stressed the importance of tailoring the widened rectum. The amount of tailoring differs in each patient. The muscles must meet posterior to the rectum. The rectum is placed in the center of the sphincteric muscle mass and anastomosed to the skin. Rectal dilation is begun gradually at 2 to 3 weeks after surgery, and the colostomy is closed in 3 months if all has healed well.

Once the urethral catheter has been removed, it is imperative to monitor the urinary tract and voiding dynamics closely because poor emptying secondary to a neuropathic component is seen in almost a third of patients. If any concern arises about the child's ability to empty, CIC should be started and continued until normal bladder dynamics are ensured. Failure to do so can ultimately result in urinary tract infection, hydronephrosis, and even loss of renal function.

Peña's TUM technique is now widely accepted for cloacal anomalies. It is a technically easier procedure that requires less time with less blood loss. The basic technique involves 360-degree mobilization of the entire urogenital sinus after the rectum has been separated. The technique at this point is not different from that described earlier for TUM for urogenital sinus abnormalities. I have found this technique to be extremely helpful. It makes the most difficult part of cloacal surgery, vaginal separation, much more easily performed when necessary. If the confluence is only 2 to 3 cm from the perineum, separation may not be even necessary. In those patients with a high vaginal confluence, separation may still be necessary but it is much more easily accomplished (Rink et al, 1997). Concerns regarding continence have been raised, but to date the results have not been different than with standard repairs. Long-term results of the TUM procedure are needed.

KEY POINTS: CLOACAL RECONSTRUCTION

- Cloacal reconstruction involves four steps: (1) decompression of the gastrointestinal tract (colostomy); (2) decompression of the urinary tract (CIC, vesicostomy, vaginostomy); (3) correction of associated organ systems anomalies; and (4) cloacal repair (PSARVUP).
- TUM is now commonly used for cloacal anomalies after the rectum is separated.
- The results of cloacal repairs are often based on the presence or absence of a normal spinal cord. CIC is frequently required, as is a bowel program, to achieve urinary and fecal continence.

Results of Cloacal Surgery

Cloacal anomalies are exceedingly challenging to repair. The anatomy is complex and differs from patient to patient. The surgeon must be prepared for a long, tedious procedure, must be imaginative, and must be willing to handle the tissues with great care. One

might assume from this preface that the results would be dismal. On the contrary, most patients lead a productive life. We surgeons are indebted to Drs. W. Hardy Hendren and Alberto Peña for their pioneering work on children with cloacal anomalies, as well as their willingness to document their results.

Results have generally been reviewed in terms of urinary continence, fecal continence, and sexual capability; in the future, results should also focus on erotic sensitivity and fertility, pain-free intercourse, and orgasm as well as quality of life. Early results from a urinary standpoint were dismal: Chappell and Bleloch (1973) reported that all 5 of their patients had some degree of incontinence postoperatively, and Bartholomew and Gonzales (1978) had 5 of 7 patients wet after reconstruction. **It is now clear that a high percentage of patients have a neuropathic component to their incontinence.** De Filippo and colleagues (1999) reported urodynamic data on 26 patients with anorectal malformations (including 6 with cloacal anomalies). Twenty-one of the 26 had preoperative leak point pressures greater than 40 cm H₂O, and 15 had normal MRI of the spine. This means that even those not demonstrating a neurologic abnormality may have abnormally high outlet resistance, which adds to the risk for incontinence and upper tract changes. Muller and associates (2014) showed that the type of spinal abnormality may impact continence rates, with the short spinal cord having the greatest impact. Of Hendren's 141 patients, 83 (59%) voided spontaneously with control, 40 (28%) required CIC, 4 (3%) had undergone urinary diversion, and 1 (0.7%) was continent with urinary diversion; only 5 (3.5%) were wet, and in 8 the results were too early to assess (Hendren, 1998). Peña and coworkers (2004) reported a review of 339 patients operated on for cloacal anomalies, 193 of whom were evaluated for urinary continence. They found that spontaneous voiding was related to length of the common channel. Overall continence with spontaneous voiding occurred in 54%. Another 46% were dry with CIC (24% with a native urethra, 22% with a Mitrofanoff channel). However, when the common channel was less than 3 cm, 28% required CIC; if greater than 3 cm, 78% required CIC. Warne and associates (2002b) achieved 80% "social continence" but only 22% spontaneously voided, 12% performed CIC alone, and 46% required reconstructive urologic surgery to achieve continence (mean number of operations, 4.7). They likewise found that those patients with a common channel longer than 3 cm were less likely to void spontaneously (12% vs. 31%). In the series by Rink and coworkers (2005b), 86% were dry but only a third were continent with spontaneous voiding. The remainder required CIC with or without lower urinary reconstruction (Table 151-1). After TUM spontaneous voiding occurred in 43% to 66% of patients (Levitt and Peña, 2010). Warne and associates (2002b) also noted that a good bladder neck, short common channel, normal sacrum, and two normal kidneys were all good prognostic signs for continence and spontaneous voiding. I am in agreement with Peña and Levitt (2003) that voiding abnormalities are generally related to a noncontractile bladder and warrant CIC, but Warne and associates (2002b) found hyperreflexia to be the predominant pattern in those with abnormal dynamics. It is important to note that 75% of their patients had an abnormal sacrum.

Fecal continence is directly related to neurologic status (Peña, 1989). Hendren (1992) noted that certain factors bode well for continence: good perineal raphe, well-defined anal dimple, normal spine, normal MRI, and brisk muscle reflex. In 105 patients, Hendren (1992) noted that 47 had normal bowel function, 27 required enemas, 7 had a colostomy, 7 had fecal soiling, and 4 with an anterior anus had normal control. Peña and coworkers (2004) reported that 60% of 156 patients had voluntary bowel movements but only 28% of them never soiled. The 40% who are fecally incontinent remain "clean" with a bowel management program. The Malone antegrade continence enema (MACE) appendicovesicostomy has been very helpful in preventing constipation and achieving fecal continence in those refractory to bowel management programs.

Late vaginal stenosis and obstructed menstruation occurred in 36% to 41% of patients (Hall et al, 1985; Breech, 2010). Warne and

TABLE 151-1 Continence Rates after Cloacal Surgery

REFERENCE	VOIDING SPONTANEOUSLY	DRY WITH CIC ± CONTINENT RECTUM
Hendren (1998)	0.62	0.34
Peña et al (2004)	0.54	0.46
Warne et al (2002b)	0.22	0.58
Rink et al (2005b)	0.33	0.53

CIC, clean intermittent catheterization.

coworkers (2003) noted the vagina to be adequate for intercourse in 44%. Revision vaginoplasty is often needed.

Although not a direct result of reparative surgery, renal outcomes are worrisome. Renal insufficiency was found in 50% of the patients treated at Great Ormond Street Children's Hospital, and 17% of the patients progressed to end-stage renal failure (Warne et al, 2002a). In the series of Rink and colleagues (2005b), 18% had an abnormally elevated serum creatinine level and in another 26% it was borderline. Lifelong yearly urologic evaluation is warranted, and prompt recognition plus treatment of any obstructive pathologic process or urinary tract infection is imperative. Bladder dynamics must be evaluated and abnormalities addressed. Of 24 reported adult patients, 17 had coitus and 6 had borne children (five deliveries by cesarean section and one vaginal delivery) (Hendren, 1998).

Leclair and associates (2007) reported on cloacal repair using the TUM technique. Urethral stenosis occurred in 2 of 22 patients and both required a Mitrofanoff catheterizable channel. One child developed a urethrovaginal fistula, and 3 had vaginal stenosis. Continence was noted in 15 of 17 patients older than 4 years of age. Seven voided spontaneously and 8 emptied by CIC. Fecal continence was present in 12, with 9 having spontaneous bowel movements and 3 requiring MACE irrigations.

SUMMARY

Management of urogenital sinus and cloacal anomalies can be exceedingly complex. In children with DSD, prompt but very careful evaluation by an expert multidisciplinary team is mandatory. Family support and education with openness and respect for the child and family are required. Differing cultural practices must also be respected and accepted. Confidentiality must be maintained. Surgical reconstruction requires great care of tissues, meticulous attention to detail, and a lifelong commitment by the surgeon. These

complex anomalies require an entire team of physicians and nurses dedicated to the care of these problems. Urogenital sinus and cloacal anomalies are very challenging reconstructive problems. Those patients at the more severe end of the spectrum should be handled only in centers with great expertise and experience.

The Process of Transition

Training Requirements

The Adolescent Clinic

Outcome Measures

DEFINITIONS

The special aspects of illness in children, as opposed to those in adults, have been recognized for centuries. In the 19th century, this was reflected in the foundation of specialist hospitals for children. A development at the end of the 20th century was the realization that many children, particularly those with major congenital anomalies, had holistic and medical needs that would continue for the rest of their lives. The problem then was to identify clinicians with the knowledge and interest to take on such care. The needs are the same everywhere, though at present the solutions are limited (Viner, 2013). Gradually, special units have appeared, particularly in Europe and Australia, to provide this service. Adolescent wards are being built, mainly in pediatric hospitals (Payne et al, 2012).

However, there is a further difficulty: children do not become adults overnight or on achieving an arbitrary birthday. **Adolescence is a phase of passing from childhood to adult life that is easily recognizable and creates unique problems in the management of chronic illness.** It has a variety of formal definitions. In the Oxford English Dictionary it is described as "between childhood and manhood (14 to 25 years old) or womanhood (12 to 21)." The Department of Health in the United Kingdom is imprecise about its beginning, but rules that its end is the 19th birthday, which means that all care must be transferred at once to standard adult clinics. Neither of these definitions is wholly satisfactory, if only because children mature into adulthood at variable rates. For example, when patients with congenital bladder disorders (mean age 20 years) were asked at what age they felt able to act independently from their parents, the mean answer was 17 years (median 16), but the range was 11 to 25 years (van der Toorn et al, 2013).

Although the need for a service to help the transition from pediatrics to adult medicine has been recognized in some specialties for 70 years or more, the main contribution of the 21st century has been the establishment of "transition clinics." Despite this, provision in the United States for long-term care remains limited (Wan, 2013). Most sub-specialties of pediatrics see the need for transition clinics, but the provision is sparse and for many chronically ill or disabled children, adult care is available only in the pediatric hospital or in a general adult clinic. The lack of facilities for long-term care is reflected in the paucity of literature on the subject. Figure 152-1 shows the number of publications in PubMed on transitional care.

The purpose of a transition clinic is to prepare children and their families for continuing medical and holistic care in the adult environment. It is predicated on the assumption that there is an adult unit to which such care may be transferred. In some chronic conditions of childhood, there is an obvious adult equivalent.

For example, a child with type 1 diabetes can eventually go to an adult diabetic specialist, but will have a need for adolescent care in the interim. Even so, good transition is frequently unavailable (Begley, 2013).

In urology there is no adult equivalent—there is no adult exstrophy, prune-belly syndrome, or disorder of sex development (DSD). Even the similarities that neural tube defects and posterior urethral valves (PUVs) have with acquired adult conditions are deceptive. **Children with major urologic conditions need care that continues for the rest of life.**

The prevalence of long-standing childhood illness in the United Kingdom is 17% to 19%. Data from other countries are limited. In the United States in 1992 it was estimated that 31% of children had a chronic condition; however, only 5% were considered to be severe and 29% moderately severe (Newacheck and Taylor, 1992). Even higher figures were recorded by Bethell and associates in 2011, but the increase was almost entirely accounted for by obesity. Excluding obesity, the prevalence of chronic disease in adolescents 12 to 17 years of age was 34.4%, of which 50% were deemed to be severe. Although no urologic condition appeared in the most common 20 conditions considered, it is clear that long-term care is a major numerical problem.

Definitions

- **Adolescence:** The period between childhood and adulthood. Specific ages are given by some authorities. In urology it is best considered as puberty to maturity as a young adult.
- **Transition:** The process of moving care from a pediatric to an adult environment. It is a difficult but essential period. Failure to manage it properly has serious consequences for the patient and for the health care system. Although it is recognized as essential, the logistics are still in the process of development.
- **Transition clinic:** A clinic staffed by pediatric and adolescent urology specialists that children attend on four or five occasions to facilitate the transfer to the adolescent clinic.

THE PROCESS OF TRANSITION

Barriers to Transition

Perhaps the most obvious barrier to movement of children with urologic anomalies into adult care is that there are very few clinics dedicated to receiving them! The conditions that will need attention in later life are of an adult nature and yet cannot be considered separately from the original congenital anomaly. This requires the services of an adult urologist who is also trained in pediatric

Figure 152-1. Papers listed in PubMed under “Transitional Care” (blue) and “Transitional Care, Urology” (red) from 1974, when the first paper appears, to 2012.

urology. At present there is no training program (see later) and few individuals are prepared to take on the financial burden of preparing themselves for a new specialty that is unlikely to attract a worthwhile reward unless there is public funding.

There are no figures available to show how many “adolescent urologists” are required. From the prevalence of the relevant conditions a total population of approximately 4 million would provide enough work for one urologist specializing in long-term care. This figure must be treated with great caution. The incidence of the given anomalies is not accurately recorded. The incidences are falling and will continue to do so as selective pregnancy terminations become more common. Nonetheless, the figure does illustrate that it is a small specialty. If there is an even distribution of age and a working life of 30 years (both doubtful suppositions), there would be a vacancy in the United Kingdom only in alternate years. In the United States there would be approximately 80 adolescent urologists.

The practical aspects of geography have to be considered. There will be far fewer adolescent urologists than there are pediatric urologists. If there is an adolescent urologist in the same city, a smooth transition should be possible. The more remotely the child lives, the more difficult will be the problem unless the family has the means and inclination to travel regularly.

In countries with some form of universal or socialized health system, it may be presumed that hospital funding would not be a problem. However, travel costs may not be refunded. In insurance-based systems, adolescents with long-term health problems are a poor commercial prospect. At least in the United States, it may be hoped that the *Patient Protection and Affordable Care Act* may help (Centers for Medicare and Medicaid Services, 2013).

The Transition Process

Children and their families are accustomed to the holistic care received in a pediatric setting. **Patients feel particularly vulnerable as they approach adulthood** (Crowley et al, 2011). Indeed, the strong attachment of the child to the pediatric staff has been shown to be a major barrier to transition (De Masi and Biermann, 2013; van der Toorn et al, 2013).

Pediatricians should start to prepare their patients at an early stage (Lemly et al, 2013). There can be no fixed time, but just the introduction of the idea that the doctor has a long-term plan is reassuring. General guidelines already exist, but remain to be validated (Colver et al, 2013; Lemly et al, 2013). Viner has identified three elements to ensure safe, effective transition. **First, a cultural shift in staff attitudes and training is required. In particular, medical practice must adapt to the needs of the adolescent and not vice versa. Second, systems must change to ensure that all pediatric chronic illness and disability services have effective transition programs in place. Third, young patients must become effective partners in their own transition** (Viner, 2008). Although he was writing about the National Health Service (NHS)

in the United Kingdom, the principles are universally applicable (Viner, 2013).

The first formal step, perhaps at 11 or 12 years of age, would be an assessment by the pediatric team of the long-term needs. At approximately 13 or 14 years of age, the child should start to attend a clinic with both the pediatric urologist and members of the team who will be taking over. This allows mutual introductions and the beginning of a medical record for adult care. It has been shown that a key factor in successful transition is continuity of care (Gleeson and Turner, 2012). At least four to five visits are required for the adolescent to build the same level of trust with the new physician that was experienced with the pediatrician (Klostermann et al, 2005). With this level of continuity of care it has been shown that, at least in diabetic adolescents, there were 23% fewer admissions compared to those with no transitional arrangements (Nakhla et al, 2009).

There then follows a transfer phase in which the consultations and decisions are made predominantly by the adolescent/adult clinicians. The pediatricians remain involved. Great care must be taken in the arrangement of joint clinics. Adolescents do not like the experience of facing a bank of clinicians together. There is also a danger that “management by committee” will lead to unsatisfactory decisions. A possible solution used in the transition of adolescents with DSD has worked well in the author’s experience. The patients are discussed by a large multidisciplinary team before the patient visit. Two or three clinicians well known to the patient (usually including a nurse specialist) then conduct the consultation. This allows a consideration of the surgical, endocrine, psychological, gynecologic, and sexual issues without a large cohort of people in the room. A critical element is to establish a dialogue on sexuality and fertility—a subject of paramount interest to the adolescent and that clinicians may be least willing to discuss.

Even this is subject to the difficulties of geography if the participants are all from different cities. To receive such specialist care, somebody has to travel. Different models are emerging. In the United Kingdom, most pediatric urology units have identified an “adult urologist” to continue the care. In the South Island of New Zealand, the relevant adult urologist travels to outlying pediatric units on a regular basis for transition and adult clinics; patients needing surgery or multidisciplinary care have to travel to the central hospital in Christchurch. In Sweden, a large country with a small population, the plan is to have two or three centers to which the patients must travel (Mark and Lackgren, personal communication, 2012).

Beyond childhood, clinicians should provide the same comprehensive care, but focused on adult life.

Consequences of Transition Failure

There are two very unsatisfactory possibilities—the child is “dumped” without any preparation or continues as a cuckoo in the pediatric nest.

Personal experience suggests that dumping has a poor outcome. In the well-structured transfer system in my practice, many patients were still lost. Those who returned in later life had sad accounts of their management in nonspecialist units. Intuitively it would be thought that a patient with a condition such as exstrophy, for example, would pose a challenge to a general urologist. However, there may well be patients who never returned and were happy with their management. In one series, 49% of potential transferees thought they could arrange their own urologic care (although only 24% knew what to expect) (van der Toorn et al, 2013).

If such patients continue their care in a pediatric hospital, it will soon cease to be pediatric—humans with a normal life span spend three quarters of their lives as adults. In a pediatric hospital in Rio de Janeiro with no transition arrangements, adolescents and adults made up 19.8% and 2.7% of outpatients, respectively (Jesus et al, 2014).

In a survey of academic pediatric units in the United States, 2% of admissions from 1999 to 2008 were of patients between 18 and 21 years of age and 0.8% were over 21 years. This gave 60,000 inappropriate admissions in the 10-year period, and there was a 6.9% annual increase (Goodman et al, 2011).

TRAINING REQUIREMENTS

There is no title, at present, for the specialist who looks after children from pediatric urology when they grow up. For want of anything better, the term *adolescent urologist* is used and understood by pediatricians and urologists. However, there is no point in having two transitions: childhood to adolescent care and then on to adult care. **Once the patient leaves childhood, it is adult physical and emotional problems that predominate and form the field of adolescent urology.**

There are three broad requirements: knowledge of the relevant anomalies in pediatric urology and their management, an understanding of the emotional and physical changes that occur in adolescence and a broad training in adult urology. The breeding ground of the adolescent urologist therefore will be in standard adult urology. Some training, perhaps a year, is needed in pediatric urology. The problem of training in adolescent medicine is unresolved. The specialty of adolescent medicine is new, and much of the training experience has been in family practice. Online training is available as a part of the NHS Health Education England program (<http://www.e-lfh.org.uk/projects/ah/index.html>).

KEY POINTS: THE PROCESS OF TRANSITION

- Children with chronic illness require life-long, holistic care, similar to the care they received as pediatric patients.
- Barriers to transition include fear of change on the part of the child and family, inadequacy of adolescent services, poor funding, and geographic problems for a small specialty, especially in large and sparsely populated countries.
- Discussion of sexuality and fertility is most important.

THE ADOLESCENT CLINIC

The huge majority of patients requiring long-term adolescent care will have one of the major congenital anomalies. Statistically, PUVs and spina bifida should account for 35% each, exstrophy approximately 5%, and others about 25%. However, the workload will be more a reflection of the complexity of the cases than the original diagnosis.

The age at which a patient transfers to the adolescent clinic must depend on the individual level of maturity. Because such clinics, at least in urology, are looking after people for the rest of their lives, the huge majority will definitely be adult. The clinical environment can be made appropriate for an adolescent, but the hospital or

clinic will be adult. In some countries, there is a legal age at which patients can be treated in an adult environment. In the United Kingdom it is 16 years of age. Patients with DSD should be seen in a separate clinic.

Most of the conditions are urologic in origin. The main exception is spina bifida. In the United States, most children with spina bifida are provided care in dedicated hospitals such as Shriners (<http://www.shrinershospitalsforchildren.org>). These are multidisciplinary units that provide an ideal environment for the management of a very difficult condition. Unfortunately, there are few replications of this for adolescents and adults. Because so many of the problems in children are with the bladder and kidneys, the long-term care is often based in urology.

As the urologic patients grow through adulthood, they have needs that go beyond the genitourinary system. It is necessary to have a group of clinicians who can share the care. Ideally, they should have an interest in the long-term care in their own fields, but this is not always possible. It is essential that they understand the idiosyncrasies of congenital urologic problems. All the conditions require the support of radiologists and nuclear medicine specialists. It is impractical to have multidisciplinary clinics with all the specialties, but so many have renal problems that a nephrologist is virtually essential for the running of an adolescent urology clinic. Table 152-1 shows the other specialists who may be needed.

There is a particular problem with psychology. Pediatric hospitals are usually well served with this specialty, but, even so, the

TABLE 152-1 Specialists Required to Support an Adolescent Urology Clinic*

CONDITION	SPECIALISTS REQUIRED
Renal anomalies	Nephrologist Physician in hypertension Transplant team
Spina bifida	Nephrologist Orthopedist Neurologist Neurosurgeon Podiatrist Gynecologist/obstetrician Geneticist Plastic surgeon

Prune-belly syndrome	Nephrologist

*All patients are likely to need the help of specialist radiology and nuclear medicine services.

demand outstrips the supply. Many surgical papers point out the need for such support (Christie and Viner, 2009). Adolescent psychology is a well-defined sub-specialty but is absolutely confined to the management of adolescents up to the age of 19 or 20. The period of true adolescence is crucial to the long-term physical and mental health of the individual. There is a change in the perceived health and social priorities that require parental, medical, and psychological support (Viner et al, 2012).

Beyond this is a huge void in the provision of psychological expertise for the chronically ill. One of the difficulties is in understanding the relationship between the strictly physical problems of an uncorrectable congenital anomaly and its psychological effects.

Geographic factors are a particular problem when arranging psychological care. The management needs frequent visits, which may not be possible if the patient lives a long way from a major medical center.

Discharge without Long-Term Follow-Up

Dischargeable Patients

Children who have had inguino-scrotal surgery, successful pyeloplasty, surgery for undescended testis and a few other conditions may be considered cured and should be discharged. Late recurrence of renal obstruction after pelvic-ureteral junction (PUJ) repair is seen in less than 3% of children and is usually symptomatic (Psooy et al, 2003). Follow-up isotope scans have shown no deterioration at a mean of 5 years (van den Hoek et al, 2007). Similarly, later development of contralateral PUJ obstruction is seen in less than 2% of patients and most of them had some preexisting dilation to give a warning (Thomas et al, 1982). Parents should be warned about the risk for neoplasia in boys with undescended testes. However, there is no evidence that any of these conditions would be avoided by continuous follow-up.

Fetal ultrasound has identified large numbers of babies with hydronephrosis. The most common diagnosis is vesicoureteric reflux, over 80% of which is in males. There is a high rate of spontaneous resolution even in high grades, with up to 40% being normal by 2 years of age (Scott, 1993). Most will be discharged in childhood. Regardless of the age at diagnosis, long-term follow-up is required only if there is significant renal failure or for the development of hypertension, the latter probably in the community.

The second most common finding is an abnormality at the PUJ that may be obstructing. The management of this problem remains a matter of debate. Of the PUJ abnormalities, 90% of mild cases and 28% of severe cases resolve in childhood (Barbosa et al, 2012; Yang et al, 2010). Those who are left with normal kidneys can be discharged.

Unresolved Follow-Up Problems

Pelviureteric "Obstruction." It is difficult to know what to do with those who have been managed "conservatively" and whose abnormality is still present. There is an obvious attraction for parents in finding that surgery is not necessary. At what point, however, can they be told that their abnormality is really a variation of normal and not a disease? This is not only of medical importance but also is important for the mundane aspects of adulthood such as obtaining life or health insurance.

Perhaps the greatest dilemma is with the symptomless hydronephrotic kidney, especially those found on fetal ultrasound. After birth, most babies are managed conservatively. On Society of Fetal Urology grading, all with grade I are likely to remain stable. The more severe the hydronephrosis, the more likely it is that surgery will be performed, so that all of grade IV and about three quarters of grade III will have undergone surgery by the age of 10 years. Approximately half of all patients will have complete resolution of the hydronephrosis (Thomas, 2010; Yang et al, 2010), and in about 20% of children the hydronephrosis remains stable to the age of 16. Thomas (2010) quotes unpublished data from Chertin and

colleagues and from Dhillon's series from Great Ormond Hospital for Children that at least up to 22 years stability is maintained.

Limited evidence is available from adult practice. In asymptomatic or minimally symptomatic patients, 10 of 50 patients deteriorated within 2 years but none thereafter up to a mean of 4.5 years (Malki et al, 2012). Patients presenting with PUJ obstruction in adulthood are presumed to have had it since birth. The patients in this series presumably had stable hydronephrosis in adolescence, and 20% later deteriorated.

At present, however, inadequate evidence exists to decide whether silent deterioration will occur later.

Hypospadias. It is well documented that the results of hypospadias repair are not as good as surgeons often report (Garibay et al, 1995; Mureau et al, 1997; Holland et al, 2001). Some surgeons have advocated long-term follow-up of children to detect poor results and correct them (Bracka, 1989; Mouriquand et al, 2011). Garibay and associates (1995) pointed out that some children who had significant obstruction of flowmetry were symptomless but benefited from diagnosis and correction.

The psychological problems encountered in children and adults with hypospadias may have been underestimated. In infancy there is evidence that surgery between 6 and 15 months of age minimizes psychological damage (Dusková and Heldlová, 1987). This timing avoids five particularly sensitive phases of psychological development, the disruption of which is thought to predispose to psychological problems in later life (Freud, 1955). Unfortunately, this remains a theoretical concept. In a series of 40 patients who underwent surgery for hypospadias who were compared to more than 10,000 unaffected controls, the risk for psychological morbidity was unrelated to the age at surgery (Mondaini et al, 2002).

There is evidence that a good surgical result does produce a happier adult, even allowing for the disagreement between surgeons and patients over the definition of "good result." The worse the surgical result and the more severe the original hypospadias, the worse is the psychological outcome (Woodhouse and Christie, 2005).

The dilemma is whether long-term follow-up alters the physical or mental outcome for adults. There are no data to help, nor would it be easy to obtain it. It might be thought that an annual visit to the surgeon for the discussion and examination of a penis that the boy thought to be normal and about surgery of which he had no recollection, might generate a psychological problem that would not otherwise exist.

Acquisition of Patients in Adolescence

A few patients develop a urologic disease in adolescence, such as pelvic cancer or a late Wilms tumor. Occasionally, a congenital anomaly such as DSD (especially the androgen insensitivity syndromes) or a PUUV may be diagnosed late.

Drug abuse is an unfortunate fact of life in adolescence. Most of those that are commonly used have some genitourinary effects (Table 152-2) (Coull and O'Brien, 2008). The most serious is ketamine. This is an anesthetic agent widely used in veterinary practice and sometimes in humans. It is a legal medication and fairly cheap. Unfortunately it is the fastest growing drug of abuse, especially in the Far East and now in Europe (Chu et al, 2008). It has a destructive effect on many organs, including causing papillary necrosis, retroperitoneal fibrosis, and a shrunken, painful bladder. Relatively small doses will produce symptoms. Two grams per day gives painful frequency in 50% of individuals and 5 g/day in 100% (Cottrell et al, personal communication; European Association of Urology, poster, 2009). Discontinuation of drug use leads to improvement, but as many as 90% may continue to have some symptoms (Cheung et al, 2011). Prolonged use leads, among other things, to renal failure and a very small bladder that is painful when full. The first line of management is to treat the addiction. It is always difficult to reform addicts, but with ketamine the additional problem is that patients find that the best treatment for their bladder pain is more ketamine (Wood et al, 2011). A small bladder will require intestinal substitution, but resumption of

TABLE 152-2 Summary of the Effects of Drug Abuse on the Genitourinary System*

DRUG	PRICE/GRAM	ACUTE	LONG-TERM
Cocaine	£50/\$75	Priapism Placental insufficiency	Impotence Penile necrotizing vasculitis
Heroin	£45/\$67	Impotence	Penile vein thrombosis
Ecstasy (MDMA)	£3.50/\$4.75 per pill	Promiscuity Polydipsia	Unsafe sex Self-harming
Cannabis	Very cheap		Inhibited orgasm Increased sildenafil use Dyspareunia
Ketamine	£20/\$30	Painful frequency	Renal and bladder destruction

*Prices are approximate, researched in 2012.

ketamine use is likely to produce similar changes in the neobladder (Ng et al, 2013).

Patterns of Long-Term Follow-Up

- *Patients not requiring follow-up:* Inguino-scrotal surgery, successful pyeloplasty, resolved reflux, and renal pelvic dilation with normal kidneys
- *Patients requiring follow-up:* Damaged kidneys (especially with a glomerular filtration rate [GFR] < 60 mL/min/1.75 m²), exstrophy, PUV, spina bifida, intestinal urinary reservoirs, anorectal anomalies, cloacal exstrophy
- *Inadequate evidence to decide:* Hypospadias, unresolved reflux or PUJ “obstruction”

OUTCOME MEASURES

Renal Function

Patients with congenital abnormalities of the kidneys and urinary tract (CAKUT) have a significant risk for renal failure in adulthood. There is a close relationship between bladder dysfunction and renal damage, especially in utero and in early infancy. In babies born with exstrophy, for example, the kidneys are almost always normal (Turner et al, 1980). Subsequent renal damage is, therefore, a consequence of surgical management. In boys with PUVs, on the other hand, it is probable that irreversible damage is done to the kidneys in utero, by the bladder dysfunction (Woolf and Thiruchelvam, 2001). This is reflected in the observation that the incidence of end-stage renal failure (ESRF) at 30 years of age in 2005 was approximately 30%, unchanged in the previous 15 years (Parkhouse and Woodhouse, 1990; Holmdahl and Sillen, 2005).

The outcome is related to the final GFR after corrective surgery. Adolescents with a GFR above 60 mL/min/1.75 m² are likely to avoid renal failure providing there are no additional renal insults. Below this level, the incidence of ESRF increases (Table 152-3) (Neild et al, 2004). Renal function is usually stable until the onset of proteinuria. Once proteinuria exceeds 50 mg/mmol creatinine (0.5 g/day), deterioration is inevitable. However, the rate of functional loss in CAKUT is slower than for other progressive forms of renal disease and rarely exceeds 3 mL/min/yr. It can be slowed, but not prevented, by angiotensin-converting enzyme inhibitors (ACEIs) (Neild, 2009). Monitoring of proteinuria and renal function at least annually is essential.

Hypertension

Damaged kidneys are the most common cause of hypertension in childhood and adolescence. Although any renal damage can lead to hypertension, the asymmetric, shrunken kidneys called *renal dysplasia* are the most common culprit (Lewis, 2008).

TABLE 152-3 Incidence of ESRF after 16 Years According to the GFR in mL/min/1.75 m² at Age of Entry*

GFR AT ENTRY	INCIDENCE OF ESRF AT 16 YEARS OF FOLLOW-UP (%)
51-60	15
41-50	35
31-40	70
15-30	90

*Usually the end of puberty.

ESRF, end-stage renal failure; GFR, glomerular filtration rate.

Data from Neild GH, Thomson G, Nitsch D, et al. Renal outcome in adults with renal insufficiency and irregular asymmetric kidneys. BMC Nephrol 2004;5:12-22.

Once renal dysplasia (reflux nephropathy) was considered a disease of girls with recurrent urinary tract infection (UTI) (Hodson and Edwards, 1960), but when adults present with asymmetrical irregular kidneys, only 10% to 20% have a history of UTI or any concomitant diagnosis in childhood (Neild et al, 2004).

The incidence of hypertension is difficult to determine partly because of selection bias in different series and partly due to different definitions. Normal blood pressure increases with age during adolescence; if only an adult definition of hypertension is used, the incidence will be underestimated. The 50th percentile for diastolic blood pressure at 16 years of age is approximately 76 mm Hg (Blumenthal et al, 1977).

If long-term monitoring of blood pressure is the only adolescent requirement, it can be done in the community, providing the facility is available and the patient is adequately motivated.

Bladder Function

The close relationship between bladder and renal function is particularly seen in spina bifida. In a long-term follow-up of an unselected group of patients with spina bifida, 50% died by 35 years of age. Of the deaths, 25% in childhood and 32% in adulthood were due to ESRF as a result of bladder dysfunction and a leak point pressure above 40 cm H₂O (Wang et al, 1988; Hunt and Oakeshott 2003). This outcome can be largely prevented by aggressive early bladder management (Dik et al, 2006).

There is also a group of patients with chronically dilated urinary tracts in whom overfilling of the bladder causes upper tract deterioration but with low pressure. In this group it is often possible to define a critical bladder volume above which the kidneys do not drain and function deteriorates. If the volume is kept below this

level, renal function is, at least, stabilized and may be improved (Hale et al, 2009).

In patients with deteriorating renal function or increasing hydronephrosis (especially in the absence of proteinuria), investigation of bladder function is essential.

Continence of Urine

The problem with continence is not so much keeping the urine in, but keeping it in and getting it out in a socially acceptable and timely manner. Despite the fact that we intuitively know what is meant by *continence*, it has proved difficult to put a concise definition in writing. The expression “the dry interval” that is widely used in pediatric practice is not acceptable to the adolescent—what happens when the interval is exceeded? With this as the definition, the answer is that leakage begins. Adolescents want to go to the bathroom when it is convenient to them and not when it is convenient for the bladder.

Much effort has gone into constructing continent storage and emptying systems. Success requires a low-pressure reservoir with a capacity of approximately 500 mL, a conduit to the outside, a means to keep the urine in, and a means to empty it. The results of the various reconstructions are discussed elsewhere.

For emptying, many rely on clean intermittent self-catheterization (CIC) first described by Lapedes and colleagues (Lapedes et al, 1972). Fortunately, this is a system that has stood the test of time (Diokno et al, 1983). In most series of patients with continent reconstructions designed for CIC, more than 90% are continent.

The artificial urinary sphincter can be used in some conditions. However, there is a significant complication rate and need for replacement (or removal), especially when the urethra has undergone reconstruction. In one of the biggest series in children and young adults with a variety of diagnoses, the half-life of the AMS 800 sphincter (American Medical Systems, Minnetonka, MN) was 15 years on a Kaplan-Meier curve, but because the mean follow-up was only 7.5 years and the maximum 17 years, the result is likely to be overly optimistic. Of the patients in one group, 86% were continent but only 22% of them were able to void, with the rest performing CIC (Herndon et al, 2003).

None of the reconstructions is perfect. All have long-term problems for which monitoring is needed by imaging and biochemical screening at least once per year.

Sexuality, Fertility, and Pregnancy

These aspects are possibly the least well dealt with in pediatric practice. Therefore it is essential to raise them early after transition. Disability must not be a barrier to normal sexuality.

Within the spectrum of conditions in adolescence there are some that are incompatible with penetrative intercourse without some reconstruction, such as aphallia or Rokitansky syndrome. There are others in which intercourse is difficult, such as exstrophy, though men still manage intercourse in 75% to 100% of cases (Stein et al, 1996; Woodhouse 1998, 1999). Ultimately, the huge majority of patients will be able to have some form of sexual activity.

With the very severe abnormalities, special efforts must be made. In patients with spina bifida there is a woeful lack of sexual education. In a review in 1999, only 5% of young adults with spina bifida thought they had received adequate sexual education (Sawyer and Roberts, 1999). Intercourse is infrequent in those with spina bifida, but 90% of girls and all men without hydrocephalus have experienced intercourse, sometimes with sildenafil (Verhoef et al, 2005). Even men with micropenis (>2.5 standard deviations below mean stretched length) largely behave in a heterosexual manner, and 60% have satisfactory intercourse (Woodhouse, 1998).

In males, fertility may be impaired through testicular failure or obstructed sperm transport. However, at least in spina bifida, if the neurologic lesion is so high that natural erections do not occur (around T12 or L1), the testes do not have germ cells (Reilly and

Oates, 1992). In practice, therefore, men with exstrophy, PUV, hypospadias, spinal bifida below L1, and unilateral undescended testis are fertile. In some, however, reproductive technology may be needed (Woodhouse, 1998). There is early, but unconfirmed, evidence that men with PUV have abnormal semen that is thick and of very high pH and may reduce fertility (Woodhouse et al, 1989).

Females are fertile if they have normal internal genitalia that have not been damaged by surgery. Girls with DSD, especially congenital adrenal hyperplasia, may have reduced fertility even with normal genitalia because of deficient hormones (Mulaikal et al, 1987; Zacharin, 1999).

Pregnancy and delivery are primarily a problem in those with an inadequate pelvis, especially spina bifida and those in whom urine is stored in an intestinal reservoir. **Joint care of pregnancy between an adolescent urologist and an obstetrician is essential.**

In women with spina bifida (and the wives of men with spina bifida), it is essential to advise supplementation for at least 3 months before conception with folic acid 5 mg/day to limit the risk for a fetus with a neural tube defect (Medical Research Council Vitamin Study Research Group, 1991). During pregnancy, urologic problems, especially infections, are magnified (Visconti et al, 2012). Cesarean section (C-section) should be done only for obstetric reasons, because there is a high complication rate and slow recovery (Arata et al, 2000).

The urine of patients with intestinal reservoirs, male and female, is positive on human chorionic gonadotropin testing for pregnancy on 56% of occasions. It is most important that this high incidence of false-positive tests is impressed on all girls at the earliest opportunity. It is important not only for women who wish to be pregnant but to avoid disaster in those who do not (Nethercliffe et al, 2001; Nakhal et al, 2012).

In women with intestinal urinary reservoirs there is also an increased risk for infection. As the uterus enlarges, ureteric obstruction may occur in approximately 10% and requires nephrostomy and stenting. The reservoir may become compressed, reducing its functional volume. Self-catheterization may become difficult. Many women prefer to leave an indwelling catheter in the pouch during the last trimester (Greenwell et al, 2003). The main risk with delivery is the need for an emergency C-section. As the reservoir and its vascular pedicle lie in front of the uterus and particularly the lower segment, there is a substantial risk that it will be damaged in emergency surgery. It is safest to do an elective C-section in all such women.

Pregnancy in women with exstrophy remains difficult. In a series of 57 pregnancies in 19 women there were 34 live births. The rate of miscarriage was high, at 35%. There were 4 still births or neonatal deaths and 4 major delivery complications. They are clearly high-risk pregnancies and require specialist care (Deans et al, 2012).

Quality of Life

As an outcome, quality of life is not easy to measure, especially in the ever-changing environment of adolescence. Most attempts in urology have either focused on the views of caregivers, rather than the patients, or asked the wrong questions. In a comprehensive review of English language publications on quality of life, Gerharz and colleagues (2003) identified 30,000 from 1980 to 1998. Of these, 3600 were about children and adolescents and only 360 asked the opinion of the patients themselves. Only two asked adolescents their opinion on a specific urologic condition.

Instruments are available to measure the several domains of quality of life. Inevitably, they are concentrated on large groups so that normative values can be defined. They can be applied to adolescents, even with rare conditions, to examine aspects such as continence and emotional well-being. Even then, there may be questions that are of great importance to a specific group but not considered in a general instrument. For example, adolescents born with exstrophy dislike the absence of a normal umbilicus and wish to avoid being treated as “abnormal.” Such concerns emerge on detailed questioning but not with quality-of-life instruments with

TABLE 152-4 Occupation Audit Results by Diagnosis^a

PUV, posterior urethral valve.

^aThis table shows the results of a questionnaire undertaken in the adolescent clinic at University College London Hospital over an 8-week period in 2010. All patients were asked to name their current occupation, which was recorded against their principal diagnosis. No patient refused to answer.

^bProfessional examples: Doctor, intensive therapy unit nurse, teacher, bomb disposal, film director, pilot, information technology (IT) academic.

^cAdministrative examples: Social worker, practice manager, bookkeeper.

^dSkilled examples: Farmer, IT technician, footballer, comedian, electrician, shoemaker.

^eUnskilled examples: Telesales, decorator, receptionist, caretaker, disc jockey, chauffeur.

^fNot-earning examples: Student, housewife, unemployed, ill.

Modified from Woodhouse CRJ, Neild GH, Yu RN, et al. Adult care of children from pediatric urology. *J Urol* 2012;187:1164–71.

which patients with exstrophy are found to be “normal” (Wilson et al, 2007).

Investigations of urinary tract reconstruction and diversion have failed to identify dramatic differences in quality of life among the various systems or even between those that are continent and those that require a stoma bag. The exception is in the domains of body image and intimacy, which are of paramount concern to adolescents and young adults. Older patients, usually being operated for malignancy, are often more phlegmatic and may prefer the simplicity of a stoma over the perceived virtues of a continent reconstruction. In the very major congenital anomalies the same views also may be present; the urologic problems may be seen as only a small component of living with a cloaca or cloacal exstrophy. In unpublished work, Liao and associates (personal communication, 2013) have shown that women born with a cloaca prefer to have a urinary system in which they can have confidence rather than one that may be less visible but more troublesome (Liao et al, 2014).

Adult urologists should be aware that, in spite of many physical and emotional difficulties, adolescents with major congenital anomalies have an overwhelming desire to be normal, to be treated as normal, and to become normal adults. Their success may be measured from a survey of occupations they achieve (Table 152-4) (Woodhouse et al, 2012). Patients view their medical care not as an end in itself, but as a pathway to a normal life.

Pretransplant Assessment

Pretransplant Preparation

Transplantation

Complications

Summary

The child requiring renal replacement will more often than not be a boy with an obstructive uropathy. The challenge for the pediatric urologist is to ensure that the damage done to the native kidneys will not be repeated with the transplanted kidney. These patients are some of the most complex children to care for, mostly in developing a therapeutic plan to provide for several goals: (1) normal urinary drainage from the kidney into a reservoir, (2) a reservoir that permits low-pressure storage for a socially acceptable time, (3) volitional emptying of the reservoir, and (4) absence of infection, (5) all with the fewest surgical procedures and patient trauma. These goals are achievable, but it must be clear that until they are ensured, renal transplantation should be deferred, or a plan to achieve them with assurance of patient and family compliance must be in place.

Patient and family understanding and compliance are essential for successful urologic management of the child with an abnormal urinary tract and end-stage renal disease (ESRD). The integration of the entire care team in this preparation is also critical and demands a close working relationship among the urology team, the pediatric nephrology team, and the transplant team. The urologist must have a basic understanding of the needs and constraints of the nephrologists and transplant surgeons, if they are not performing the entire transplant. The ureteral implantation can be performed by the urologist or the transplant surgeons, but this should be dependent on the state of the bladder and the comfort level of the surgical teams with the particular aspects of the surgery and their postoperative management, including any complications.

PRETRANSPLANT ASSESSMENT

Screening

A large fraction of children in need of renal replacement will have some type of uropathy—congenital obstruction, vesicoureteral reflux, or neuropathic bladder dysfunction (North American Pediatric Renal Trials and Collaborative Studies [NAPRTCS], 2008; Van Arendonk et al, 2014). Younger boys will typically have obstructive uropathy, including posterior urethral valves, whereas the reflux and neuropathic bladder patients will be older, including young adults. Some children will have uncharacterized ESRD, and it is reasonable to have all children screened for urologic issues before transplant. A detailed history, renal ultrasonography, and postvoid residual urine volume by ultrasonography can effectively rule out most significant uropathies. Routine voiding cystourethrogram (VCUG) is not necessary unless there is a history of a specific urologic disease, febrile or recurrent urinary tract infection (UTI),

hydronephrosis, or clinically abnormal voiding (Ramirez et al, 2001; Singer et al, 2009) (Fig. 153-1).

Focused Assessment

The child with a known urologic abnormality will require a pretransplant assessment directed by the underlying condition and the status of the bladder and kidneys. In most, a VCUG will be useful to permit an assessment of voiding function, the state of the urethra, and the presence of reflux. When bladder dynamics are abnormal based on the VCUG or a renal sonogram, consideration for urodynamic evaluation is appropriate. The indications for urodynamic testing to assess bladder capacity, compliance, and emptying, as well as sphincter function, include a known neuropathic bladder abnormality, prior severe posterior urethral valves, and any ongoing voiding dysfunction, hydronephrosis, or recurrent UTI (Burns et al, 1992; Zermann et al, 2003; Riley et al, 2010). The principal goal of the urodynamic testing is to determine the need for further therapy for bladder function. This might include medical therapy with anticholinergics, the use of intermittent catheterization, and the potential need for bladder augmentation in severe cases.

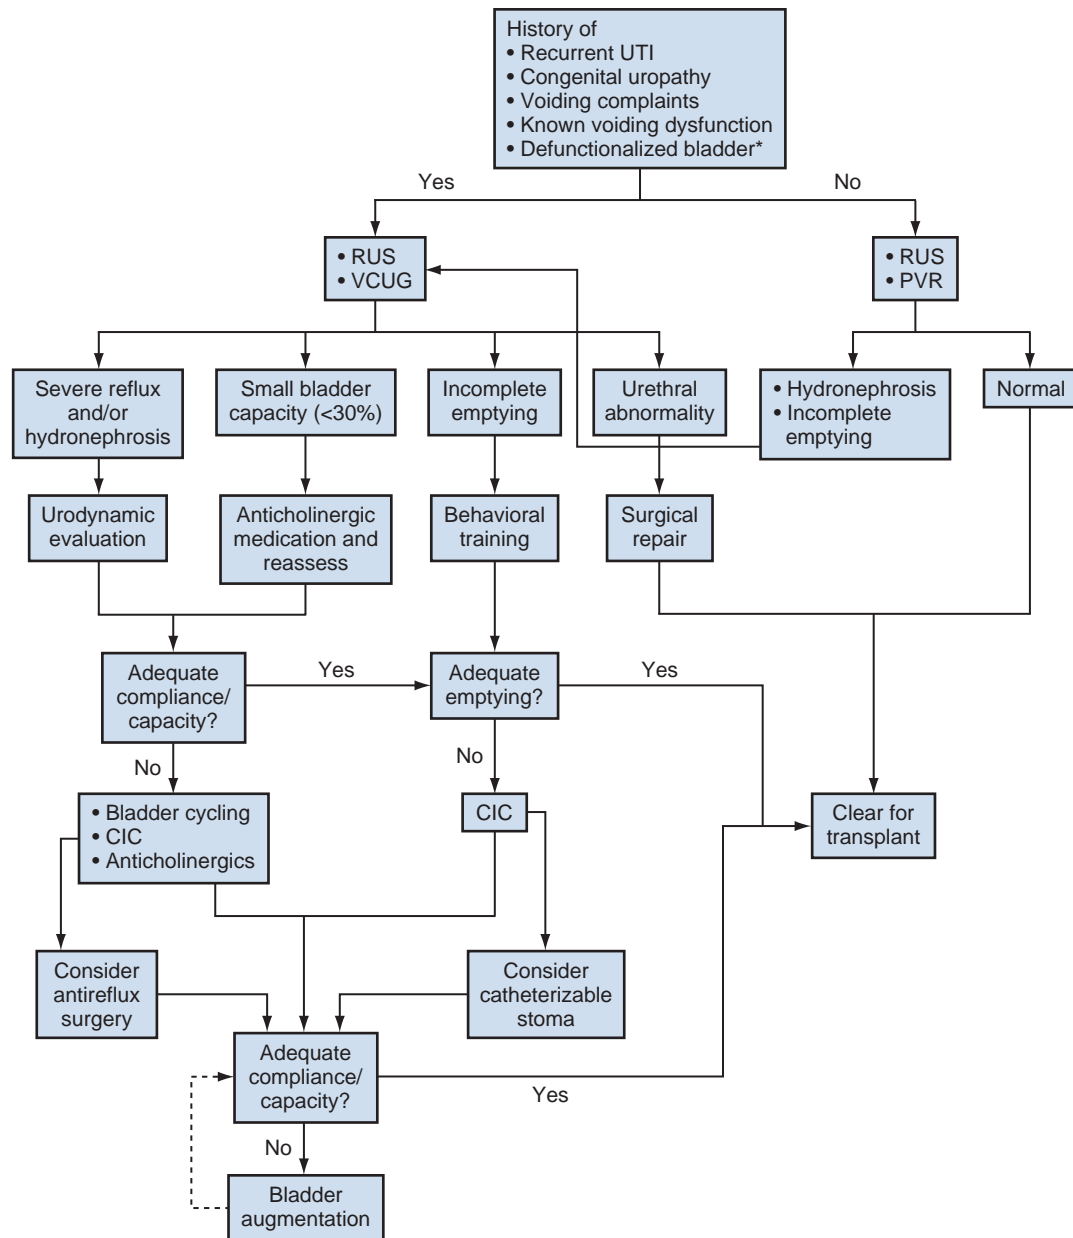

Urodynamics will also provide insight into bladder emptying function, which will be critical to prevent infection. Of course, if medical therapy for a noncompliant bladder is needed, this may impair bladder emptying and necessitate clean intermittent catheterization (CIC) to permit effective emptying. In the sensate child or in some with neuropathic bladders, the creation of a continent catheterizable stoma may be the ideal way to facilitate effective CIC. These decisions should be made and executed before transplant. Urodynamic evaluation will often be a regular monitoring evaluation in these children, and a critical element in ongoing optimization of bladder function. It will often be necessary to repeat the study to ensure that the therapeutic intervention has been effective and that the bladder is prepared for the transplant.

PRETRANSPLANT PREPARATION

Bladder Preparation

General Issues

The most common bladder abnormality associated with ESRD is the low-capacity, hypertonic bladder with poor compliance. This is the typical picture with posterior urethral valves, but it is important to recognize that these bladders continue to evolve and may

*If patient is anuric and has no urologic history, no further testing is essential; if there is a history of neurogenic bladder, posterior urethral valves, or complex urologic condition, consideration of bladder cycling and anticholinergics is appropriate.

Figure 153-1. Algorithm for evaluation and management of the bladder in patients in preparation for renal transplantation. The key element is the history of urologic conditions or symptoms. CIC, clean intermittent catheterization; PVR, postvoid residual; RUS, renal ultrasonography; VCUG, voiding cystourethrogram.

progress to a pattern of insufficient contractility to empty at all (Peters et al, 1990; Nguyen and Peters, 1999). They may still be hypertonic and pose ongoing renal risk and will require CIC in most cases. Hypertonicity is the most dangerous dynamic pattern because it will create an obstructive condition for the kidneys, even in the absence of reflux. Bladder dysfunction can increase graft loss (Herthelius and Oborn, 2007).

Hypertonicity

The hypertonic bladder is managed with medication as a first line, typically with anticholinergics, and with augmentation as the second line (Lopez Pereira et al, 2000). Medical management

requires diligence on the part of the family and follow-up that regularly assesses the response to therapy. It will usually require a combination of anticholinergics and CIC, although some children with posterior urethral valves can learn to void by Valsalva maneuver. It should never be assumed that they will be able to do so; they must demonstrate this by repeated low postvoid residual volumes on catheterization.

Anticholinergic therapy is best titrated with increasing doses, and watching for a change in catheterized volumes, wetting, and hydronephrosis. Urodynamic evaluation can more precisely define the efficacy. Often, medical therapy is introduced at the same time as CIC, although this is not essential. Compliance with CIC is often an excellent test of future patient and family compliance with the

KEY POINTS: UROLOGIC EVALUATION AND MANAGEMENT

- Goals:
 - Normal urinary drainage from the kidney into a reservoir
 - A urinary reservoir that permits low-pressure storage for a socially acceptable time
 - Volitional emptying of the reservoir, with continence
 - Absence of infection
 - The fewest surgical procedures and patient trauma
- A large fraction of children in need of renal replacement will have some type of uropathy—congenital obstruction, vesicoureteral reflux, or neuropathic bladder dysfunction.
- Pretransplant assessment is directed by the underlying condition and the status of the bladder and kidneys.
- Urodynamic testing aims to assess bladder capacity, compliance, and emptying, as well as sphincter function.
- Indications for urodynamics include a known neuropathic bladder, prior severe posterior urethral valves, and any child with ongoing voiding dysfunction, hydronephrosis, or recurrent UTI.

stringent requirements of renal transplant. If a family is unable to manage with CIC, their ability to manage medical care after a transplant should be questioned.

The goal of therapy is for the child to be able to hold up to capacity for age, at low pressure (<30 cm H₂O). I have had some success at teaching parents with children on CIC to measure the opening pressures at catheterization by estimating the height of the water column in the catheter. This may be a more natural measurement, although the strict correlation with outcomes has not been defined.

Capacity

Bladder capacity is another element of normal function and is the basis for both safe storage and social continence. Bladder capacity can be improved with anticholinergic medication but may ultimately require bladder augmentation. There is a clear shift away from augmentation in all patients, and there have been prior reports that augmentation is not needed in renal transplant (Alfrey et al, 1997; Salvatierra et al, 1999). Augmentation remains a necessary aspect of urologic management in children with complex uropathies with ESRD. Current indications would include nonsalvageable bladder (exstrophy, tumor, severe end-stage neuropathic bladder) or failure of medical and CIC therapy to achieve low-pressure storage for up to 3 hours. If pressures are safe for 1 hour only and the rest of the time they exceed 40 cm H₂O despite aggressive medical and catheterization therapy, consideration for augmentation is important.

There is no evidence, nor logic, that bladder augmentation in itself increases the risk of transplant, despite some reports (Alfrey et al, 1997), and indeed, it has permitted many effective transplants into very abnormal bladders (Sheldon et al, 1994; Koo et al, 1999; Luke et al, 2003; Taghizadeh et al, 2007; Djakovic et al, 2009; Broniszczak et al, 2010). There is no single approach that is ideal, although gastric augmentation gained popularity for ESRD children in the late 1980s and early 1990s. It offers the benefit of secreting acid in a patient who is typically acidotic, it can limit infection, and it has a lower rate of bladder stones (Traxel et al, 2011). Gastric augmentations, have, however, been linked with severe complications, particularly in the pretransplant anuric group, because of gastric juice injury of the native bladder segment and because of the fairly common hematuria-dysuria syndrome (Reinberg et al, 1992; Nguyen et al, 1993). Reports of malignancy, particularly in the transplant group, are worrisome, but are still too anecdotal for practice to be changed (Castellan et al, 2007; Husmann

and Rathbun, 2008). Caution and monitoring are essential. Composite gastric augmenting patches are useful and may have less morbidity. Ileum and sigmoid are all useful and may be more appropriate in some patients, depending on anatomy, prior surgery, and preferences for continent catheterizable stomas.

The augmented patch rarely will create an issue with the transplant, but the fact of the pedicle being present and its anatomic orientation must be recognized by the transplanting team. Similarly, continent stomas should be placed in such a location as to avoid conflicting with the anticipated transplant incision(s), and nearly always may be positioned medial to these. Again, recognition of the location and presence of the mesentery for the stoma is important.

The infant receiving a transplant may have an aortic anastomosis to the renal vessels, which will create a potential need to mobilize the mesentery of the augment or stoma. Coordination between the reconstructive and transplant teams is essential.

Infections

Many children with complex reconstruction of the urinary tract will have a history of recurrent UTI. This may be associated with intermittent catheterization. This is a potential hazard for the transplant, and pyelonephritis of the graft is certainly associated with graft loss (Dunn et al, 1987; Hanevold et al, 1987; Neuhaus et al, 1997; Howie et al, 2002; Herthelius and Oborn, 2007). The underlying cause of the infection is most likely inadequate emptying of the reservoir, either by catheterization or voiding, or urinary obstruction with hydronephrosis (Chu et al, 2013). This needs to be assessed and addressed in advance of the renal transplant. Strategies include double and triple voiding to avoid using CIC or, if CIC has already been instituted, ensuring adequate emptying or teaching proper methods to ensure emptying. In general, UTIs are not seen to present a major threat to the renal graft as long as they are managed appropriately (Fallahzadeh et al, 2011; Traxel et al, 2011).

Persistent UTI in the face of appropriate technique for CIC suggests either an anatomic abnormality that has not been detected or chronic colonization. The latter will sometimes respond to long-term antibiotic courses using agents including the fluoroquinolones and cephalosporins. The etiology and specific therapy for this situation are uncertain. Anatomic abnormalities such as diverticula may require more specific imaging studies but may be amenable to surgical cure, including a bladder diverticulum or nondraining ureteral stump; these are uncommon.

Clean Intermittent Catheterization

The use of CIC in managing the abnormal bladder has been a truly revolutionary lifesaver in the last four decades. Although it may be a challenge to initiate, once started it is nearly always well accepted. Careful preparation, teaching, support, and follow-up are critically important for long-term success.

The importance and principles of CIC must be well understood by the care providers and carefully communicated to the family, including all possible caregivers. The recognition that this is a means by which to reduce infection and attain both safe bladder storage and control over voiding is very important and yet may not be readily apparent on first pass.

The frequency of CIC must be determined by a measure of approximate urine outputs, as well as storage pressures based on urodynamic assessment or by home-catheterization opening pressure measurements. This permits an estimate of safe pressure-volume relationships for day-to-day life. Avoiding regular excesses of these volumes and therefore high pressures will facilitate healthy kidney function. The typical frequency is between 3 and 4 hours. Pressures should not exceed 40 cm H₂O for any prolonged period of time.

Initiating CIC in preparation for transplantation serves an assessment purpose as well. For families in which follow-through may be imperfect, CIC is a useful means of determining their commitment and ability to follow complex medical care plans. If CIC

cannot be instituted before transplant to manage an abnormal bladder, there is no reason to believe this ability will suddenly appear after transplant. **The response to CIC can predict the ability to manage the necessary transplant medication and care regimen as well.** The committed and understanding family will manage well, and this will serve to demonstrate their readiness for transplant.

The Defunctionalized Bladder

Neuropathic Bladder

The defunctionalized neurogenic bladder is becoming scarce because of better management but will occasionally manifest clinically in a transplant patient who has not had ongoing urologic care (Firlit, 1976; Serrano et al, 1996). **It is impossible to know without testing what the potential function of the bladder may be. It is also important to recognize that the bladder that has been defunctionalized will take some time to reach its maximal functional potential. This is often best accomplished by bladder cycling to increase capacity, determine bladder wall compliance, and assess the family's ability to perform CIC.**

Some have advocated simply implanting the transplant ureter into the bladder and anticipating normal function (Salvatierra et al, 1999). Although this may occur on rare occasions, it is a highly risky approach to the chronically defunctionalized bladder.

Cycling the defunctionalized bladder is best accomplished through a progressive program of catheterization with instillation of increasing volumes of saline, with a set dwell time and then catheter drainage (Alam and Sheldon, 2008). The amounts will be determined empirically based on initial tolerated volumes and should increase at regular intervals, usually 10 to 15 mL per day. The response to these instillations will give useful clues as to the utility of the bladder as a reservoir and any ability to empty spontaneously. Adjunctive anticholinergic medications are often necessary to increase bladder capacity and compliance.

The defunctionalized neurogenic bladder will almost certainly require intermittent catheterization for emptying. It is therefore reasonable to introduce this to the family. In the rare instance wherein the child can learn to empty satisfactorily, CIC may no longer be needed. This is a major step and requires a careful study of voiding diaries, postvoid testing, and assessment of the upper renal tracts.

The target volume is the anticipated capacity for age based on any of the available formulas (Koff, 1983; Kaefer et al, 1997). This may not be reached immediately, but if volumes increase steadily without significant leakage, further expansion is likely. Although storage capacity is important, compliance is equally critical, and this must be assessed formally with urodynamics. Only if capacity and compliance parameters near normal can be reached should the patient be cleared for transplant. Aggressive medical management is also important in this determination. If adequate storage and compliance cannot be attained, consideration for augmentation must be entertained. This should be performed before transplant unless there are pressing reasons.

Non-Neuropathic Bladder

The defunctionalized bladder associated with renal insufficiency is often attributable to posterior urethral valves or vesicoureteral reflux. These bladders may be more often salvaged to ultimately permit spontaneous voiding but should initially be approached as defunctionalized neurogenic bladders, with the assumption that CIC will be needed long term. The critical factor will be the storage capacity, and progressive cycling as described earlier can provide that assessment. At the same time, children can be asked to attempt to void after holding the instilled saline for a period of 15 or 20 minutes. Postvoid catheterization then is used to determine the postvoid residual volume.

The ability to empty spontaneously will also affect the decision regarding the need for a continent catheterizable stoma. This is more critical in boys with normal sensation, who may be

very resistant to urethral catheterization. The period of pretransplant CIC will permit assessment of both voiding ability and tolerance of urethral CIC. These decisions are best made concurrently with other reconstructive choices to permit an integrated strategy and a single surgical procedure if possible.

The Decision to Augment

Although the use of bladder augmentation is declining because of concerns regarding metabolic, infectious, and neoplastic complications, enterocystoplasty remains the most effective means to provide normal bladder storage function in both neurogenic and postobstructive bladder dysfunction (Barnett et al, 1987; Sheldon et al, 1994; Hatch et al, 2001; Nahas et al, 2002; DeFoor et al, 2003; Capizzi et al, 2004; Mendizabal et al, 2005; Rigamonti et al, 2005; Aki et al, 2006; Traxel et al, 2011). To lose a renal graft as a result of the same processes that contributed to native renal demise is unacceptable. The potential complications of augmentation must also be clearly recognized and anticipated, although some reports have presented extreme examples that are not my experience (Alfrey et al, 1997). A strategy of aggressive intermittent catheterization with medical management becomes the best approach to identify patients in whom augmentation is the only real option for successful renal transplantation. It is difficult to determine a meaningful incidence of the need for augmentation, because the effort expended by both family and health care team varies as much as the underlying pathology. With early aggressive bladder management, the need for augmentation in both neurogenic and obstructive bladder dysfunction has been declining.

Broad indications for augmentation before transplantation would be the inability to develop capacity greater than 75% of expected for age with pressures below 30 cm H₂O, using catheterization that is no more frequent than every 3 hours and using maximal anticholinergic medications. Tolerance to medication will obviously be an important element of these criteria. These thresholds are rules of thumb without strong clinical data to support them. Exceptions can be found wherein bladder capacity improves markedly after transplant, perhaps because of the effects of uremia, but they should serve as guidelines for determining when to augment before transplantation.

The availability of a dilated ureter to permit ureterocystoplasty (Kim et al, 1996; Landau et al, 1997; Kurzrock et al, 2002) should be explored, although results have been mixed. It is preferable to perform enterocystoplasty in this context, and efforts should be made to preserve the ureter when possible for this use, or for a continent catheterizable channel.

KEY POINTS: PRETRANSPLANT PREPARATION

- The most common bladder abnormality associated with ESRD is a low-capacity, hypertonic bladder with poor compliance.
- There is no evidence that bladder augmentation increases the risk of transplant.
- Recurrent pyelonephritis is a potential hazard for the transplant and is associated with graft loss.
- Initiating CIC in preparation for transplantation serves an assessment purpose as well as facilitating bladder emptying.
- Bladder refunctionalization is often best accomplished by bladder cycling to increase capacity, determine bladder wall compliance, and assess the family's ability to perform CIC.

Cutaneous Stomas

The defunctionalized bladder may be associated with a variety of urinary diversions, including ileal and colon conduits, as well as

ureterostomies. In the past, transplantation was performed with the ureters draining into the diversion. This is rarely appropriate today, although it remains an option, but UTIs are frequent (Broniszczak et al, 2010). A functioning ileal loop diversion in the setting wherein augmentation is determined to be necessary can be used as the augmenting patch with bladder refunctionalization, even if the patient is anuric. If augmentation is not needed, based on CIC cycling, and the patient continues to make urine and the native kidney will not be removed, it should be implanted to refunctionalize the bladder, and the loop discarded. If there is uncertainty regarding the need for augmentation, the loop may be preserved to be available for augmentation after transplant if essential.

Reconstruction Strategies

If bladder reconstruction will be needed, several factors must be considered in anticipation of the ultimate renal transplant. These considerations reflect the type of dialysis (either hemodialysis or peritoneal dialysis), likely placement of the graft, timing relative to both initiation of dialysis (if not already begun) and transplantation, the need for bowel surgery, and the native kidneys. Consideration of these factors will permit a more coordinated and efficient reconstruction.

Dialysis Issues

If a patient is already on peritoneal dialysis, any intraperitoneal surgery will likely require temporary transition to hemodialysis. Limiting this to one procedure is valuable. At times this can be linked with placement of a peritoneal dialysis catheter, but if bowel surgery is needed, this may increase the risk of infectious complications.

If the patient is not yet on dialysis but is approaching the need, there may be some consideration for initiating dialysis before reconstruction to improve the overall medical status of the child. This can promote more rapid wound healing and fewer complications. At the same time, this will affect the child on peritoneal dialysis as noted, and for those on hemodialysis, there is a risk of fistula injury during surgery because of low flow states, as well as direct pressure.

Graft Placement

Consideration should be given to the likely location of the graft. In the very small child in whom the graft will be placed intraperitoneally on the aorta, careful movement of any mesenteric pedicles away from the midline is advisable, as is trying to avoid a transuretero-ureterostomy. A psoas hitch for ureteral reimplantation of the native kidney, if it is to be salvaged, can make ipsilateral iliac graft placement difficult. There may be no feasible alternatives, and in such cases, careful documentation of the procedure is essential.

Timing

In general, any major urologic reconstruction should be undertaken well before anticipated transplantation (Taghizadeh et al, 2007). Minor ureteral surgery may be considered at the time of transplantation, but this is unusual. After enterocystoplasty or continent diversion, at least 6 weeks is needed for healing and 3 months would be preferable. Unilateral native nephrectomy is reasonable at the time of transplantation, but only in older children. Operative time in the infant may have more of a negative impact on graft function, and it seems imprudent to add this extra risk.

Enterocystoplasty

Enterocystoplasty in the setting of a dialysis patient or a child approaching ESRD is feasible and, when needed, can be successfully accomplished in a manner similar to that in any other child (Sheldon et al, 1994; DeFoor et al, 2003; Taghizadeh et al, 2007). The selection of bowel segments and reconstructive strategy

should be based on the functional anatomy and needs of the individual child. These include factors such as the need for a continent catheterizable stoma, the availability of native bladder tissue, the status of the bladder neck and continence mechanism, and bowel function. **If continent diversion is needed because of an unsalvageable bladder, there is no reason to defer this until after transplant.** The often-quoted contraindication to continent diversion in the setting of renal impairment is not applicable to these patients. They will need medical management of the metabolic effects of the diversion, but they require aggressive metabolic management at baseline. In some cases, by improving bladder dynamics and limiting infection, the progression to end-stage disease may be delayed.

The use of gastric segments was considered particularly appropriate for the child approaching end-stage failure and in selected patients can still be useful (Burns et al, 1992; DeFoor et al, 2003; Traxel et al, 2011). Because of the various complications of gastrocystoplasty, however, this approach has been used much less. The benefit of acid excretion for the child with chronic kidney disease can be helpful, but these children are also at risk for complex metabolic derangements with alkalosis. For the anuric child, the presence of gastric secretions in the empty bladder can lead to erosion and even perforation (Reinberg et al, 1992). Care must be taken in those children to use proton pump inhibitors and to irrigate with bicarbonate solutions until urine output is restored.

Native Nephrectomy

The decision regarding native nephrectomy must be made as a multidisciplinary team involving nephrology and urology providers as well as the family. There is controversy in this regard, and although in general it is preferable to leave the native kidneys (Fraser et al, 2013), **there are several situations where removal pretransplant is necessary. These include malignant hypertension, profound nephrotic syndrome with malnutrition from protein losses (Kim et al, 1992), recurrent upper tract infection, and massive reflux.** The last may be more relative, but with stasis and possible infection in an immunosuppressed child, removal is preferable and less risky. The usefulness of leaving a native kidney that produces some urine is in making dialysis more manageable with fewer fluid restrictions. This can facilitate nutritional support in the younger child. This must be balanced against the possible risks of infection and hypertension, as well as graft function.

In the infant undergoing renal transplantation, native nephrectomy is strongly recommended by some groups to enhance graft survival based on improving blood flow to the graft. Any shunting of blood from the graft in a small child, whose cardiac output may be a small fraction of that of the adult from whom the graft came, may potentially impair early graft function.

In a child in whom native nephrectomy is to be performed, the principal contributing factor is whether peritoneal dialysis is being performed. If so, laparoscopic transperitoneal removal will require temporary hemodialysis. Some have performed immediate peritoneal dialysis, but the risks of leakage with possible infection would argue against this practice. Retroperitoneoscopic nephrectomy can be performed with immediate peritoneal dialysis (Gundeti et al, 2007), but leaks may still be encountered. If the kidneys are small, then this is the optimal approach. For large kidneys in children on peritoneal dialysis, posterior open nephrectomy may be the overall optimal approach.

If peritoneal dialysis is not being performed, then any type of nephrectomy is acceptable. The incidence of postoperative adhesions is limited and is unlikely to affect the efficacy of peritoneal dialysis. There is the potential impact on the ultimate transplant procedure when the distal ureter is to be removed, because this will cause adhesions in the area of the iliac vessels. However, if there is significant reflux or obstruction and a dilated ureter, total removal may be best to limit the risk of infection. Renal embolization has been reported as an alternative to surgical nephrectomy (Capozza et al, 2007).

KEY POINTS: PRETRANSPLANT RECONSTRUCTION

- The ability to empty spontaneously will also affect the decision regarding the need for a continent catheterizable stoma.
- Indications for augmentation before transplantation include the following:
 - Capacity less than 75% of expected for age
 - Pressures below 30 cm H₂O
 - Catheterization every 3 hours
 - Maximal anticholinergic medications
- For patients on peritoneal dialysis, intraperitoneal surgery will likely require temporary transition to hemodialysis.
- In general, any major urologic reconstruction should be undertaken well before anticipated transplantation.
- Native nephrectomy is indicated for patients with the following:
 - Malignant hypertension
 - Profound nephrotic syndrome with malnutrition
 - Recurrent upper tract infection
 - Massive reflux

Managing Native Kidneys***Avoiding Removal***

In the absence of specific indications for nephrectomy, leaving the native kidneys offers the advantage of having a potential source of water excretion if the graft fails. Although this can be helpful in managing nutrition and lifestyle, it should not become a rigid goal if there are reasons to remove the kidneys. Their ultimate utility may be very limited, particularly after a period of graft function, because they often will regress in size and urine output.

Limiting Risk of Infection

Urinary infection in the setting of an immunosuppressed child with a renal graft is damaging to both child and graft. Preventing infection in the child with known urologic concerns is therefore a priority; interventions should be performed proactively, rather than purely in response to an infection. The damage from one infection may be critical to that child. Situations in which active prevention of infection may be useful include high-grade reflux, persisting hydronephrosis (Chu et al, 2013) with or without reflux, and, particularly, the need for intermittent catheterization. These patients are frequently colonized with bacteria and may be more susceptible to UTI. The nondilated, nonrefluxing native kidney is unlikely to be subject to infection and can usually be maintained in the absence of other indications for removal.

Ureteral Preservation

When nephrectomy is to be performed, ureteral preservation should be considered. If the ureter is normal, it should always be left to limit surgical dissection near the iliac vessels and to have an option for proximal transplant to native ureteroureterostomy for distal ureteral stenosis (Kockelbergh et al, 1993; Lapointe et al, 2001). If bladder function is abnormal and intermittent catheterization may be needed, preserving the ureter for use as a continent stoma is advisable. This is best performed pretransplant. Creation of the continent stoma at the time of transplant is an option.

Combining Nephrectomy and Transplant

Native kidneys may be removed at the time of the renal transplantation, but this is usually avoided to limit surgical complexity and time. It may be appropriate for a single native kidney, which may be swiftly removed through the transplant incision. In the absence of specific justification, however, this strategy in general is to be avoided.

TRANSPLANTATION

The technical elements of the vascular component of the transplantation are described in Chapter 47 and are appropriate to children. One exception may be transplantation into the infant wherein the vascular anastomoses are performed on the aorta. This usually is performed with anticoagulation, which may affect bladder surgery. More care with hemostasis is needed. For the pediatric urologist who is not performing the vascular anastomosis, the ureteral anastomosis becomes the focus of attention, as well as of complications.

Ureteral Anastomosis***Surgical Techniques and Options***

As with ureteroneocystostomy for vesicoureteral reflux, there are intravesical and extravesical techniques for the transplant ureteral anastomosis. I have attempted to perform an antirefluxing anastomosis in all cases, although it is clear that this is not essential. Although careful screening can identify patients who have bladder dysfunction and therefore are at risk for graft reflux, the method to prevent reflux is simple and effective and associated with minimal morbidity.

Extravesical ureteroneocystostomy is the preferred ureteral anastomosis. After the vascular anastomoses have been performed and hemostasis has been achieved, the bladder is partially filled with saline or a dilute antibiotic solution. The anterolateral aspect is cleared and traction sutures are placed to mobilize the lateral aspect upward and to provide tension on the vesical wall. The ureter is sized to ensure it will reach. The detrusor is incised to the level of the mucosa for a length of about 3 to 3.5 cm in a horizontal direction. Flaps of detrusor are elevated away from the mucosa and a small disc of mucosa is excised at the distal aspect of the trough. The bladder will drain and the traction sutures keep the trough in position. The ureter is trimmed loosely to length and spatulated for 4 to 5 mm. An interrupted, mucosa-to-mucosa anastomosis is performed using a fine absorbable suture. A monofilament is preferred. The detrusor flaps are then brought over the ureter. No advancement stitch is used, but two stitches are placed through the detrusor and the adventitia of the terminal ureter to prevent eversion of the ureter. The detrusor is closed with interrupted absorbable suture.

Alternatively, the widely used Barry technique (Barry, 1983; Barry and Hatch, 1985) may be used, whereby a 4-cm tunnel is created between parallel incisions through which the ureter is passed. A shorter tunnel has been used in some pediatric centers with reported success in small numbers (Vasdev et al, 2011).

If the bladder wall is particularly abnormal and thick, a longer tunnel is developed and the flaps are dissected back a bit further to provide a more robust antireflux tunnel and limit the risk of obstruction, as these are typically abnormally functioning bladders. Implanting the graft ureter into an augmented bladder poses further challenges, and it is preferable to perform the ureteroneocystostomy into the detrusor. On occasion this has necessitated an intravesical approach through the augment to reach the detrusor, which may be impossible to mobilize effectively otherwise. If there is no detrusor available, anastomosis into a colonic or gastric segment is preferable. It would always be advisable to perform a nonrefluxing ureteroneocystostomy in these settings, because these patients are inevitably on intermittent catheterization and often colonized with bacteria.

I no longer perform a routine open-bladder ureteroneocystostomy for transplant, but a modified Politano-Leadbetter procedure is an effective method. It does introduce a large cystotomy and bladder spasms. In the unusual setting in which this is considered appropriate, there is no specific need for stenting beyond the indications described later.

Transplant to native ureteroureterostomy is performed routinely in a few institutions for pediatric renal transplantation. Results have been reported as acceptable (Lapointe et al, 2001; Gurkan et al, 2006), but this does not seem to be a common

option, and of course its use depends on the availability of a normal, nonrefluxing native ureter. This option is available as a salvage procedure in the setting of distal ureteral stenosis.

Ureteral Stenting

The role of routine ureteral stenting in pediatric transplant is debated, but there are no data to demonstrate its routine usefulness (French et al, 2001; Simpson et al, 2006; Dharnidharka et al, 2008). It has not been the routine for me, but there are situations in which ureteral stenting is appropriate. These situations would include the difficult implant, particularly in an abnormal bladder or with a very damaged graft ureter. In adult series, stenting showed an advantage for cadaveric donors in terms of reducing the incidence of ureteral complications from 5.8% to 1.9% but had an increased risk of infection (Fayek et al, 2012). If a stent is to be used, a short double-J ureteral stent is placed and typically is removed in 4 weeks. This obviously requires a cystoscopy. I have not used extraction strings for children undergoing stented transplants.

KEY POINTS: TRANSPLANT URETERONEOCYSTOSTOMY

- Extravesical ureteroneocystostomy is the preferred ureteral anastomosis.
- Transplant to native ureteroureterostomy is an effective option.
- There are no data to support routine ureteral stenting at the time of transplantation.

COMPLICATIONS

The urologic complications of pediatric renal transplantation are discussed in this section. Those related to the graft directly, including vascular and rejection issues, are dealt with in Chapter 47. Table 153-1 presents a summary of reports of urologic complications in pediatric renal transplantation. The unique analysis of Khositseth and colleagues comparing the incidence of urologic complications in transplant recipients having a history of obstructive uropathy or

reflux with the incidence in those without that history shows the increased risk of all urologic complications in patients with preexisting uropathy (Khositseth et al, 2007). Posterior urethral valves are associated with an increased risk of graft dysfunction in some series (Luke et al, 2003; Adams et al, 2004), but not in others (Nuininga et al, 2001; Fine et al, 2011; Kamal et al, 2011). In nearly all series, however, obstructive uropathy is associated with a higher risk of urologic complications. Special vigilance and a lower threshold for intervention are appropriate in this population.

Urine Leaks

Urine leaks are typically identified in the early postoperative period with increasing fluid from the wound drains. The fluid creatinine level can reveal if this is a urine leak as opposed to lymphatic drainage. At first presentation, it is critical to assess all urinary drainage tubes, particularly the Foley catheter. If the catheter has been removed, it is often best to replace it. A transplant sonogram is performed to determine if there is hydronephrosis, although its absence does not rule out obstruction. If hydronephrosis is present, distal ureteral obstruction should be suspected and consideration for a percutaneous nephrostomy should be entertained. The level of the leak must then be determined, and either a mercaptoacetyl-triglycine (MAG3) scan (assuming adequate graft function) or a computed tomography (CT) scan can be effective. A cystogram may be useful to identify a bladder leak from the site of the anastomosis.

The indications for intervention are clinically based, and if the leak is limited, an observational approach is reasonable. I have seen leaks in the setting of very high post-transplant urine output in smaller children caused simply by a small bladder catheter. If a larger catheter may be placed, this may facilitate resolution. If there is significant urine leak despite adequate bladder drainage, exploration may be needed.

Exploration is to identify the cause and location of the leak and provide for repair. If the leak is bladder based, the use of simple repair and drainage is effective; but if the leak is a result of distal ureteral necrosis, some means of ureteral replacement is needed. For a short segment of necrosis, bladder mobilization and reimplantation is effective. If a long segment of ureter has been lost, native ureter, either ipsilateral or even contralateral, may be useful if available. A psoas hitch or bladder flap may be needed if the native ureter is not present. These strategies are similar to those used

TABLE 153-1 Urologic Complications in Pediatric Renal Transplantation

AUTHOR AND YEAR	PATIENTS	URETERAL STENOSIS	URINARY LEAK	VUR	STONE	COMMENT

Figure 153-2. Ischemic loss of the entire renal pelvis and ureter in a cadaveric renal graft into a patient with a gastrocystoplasty. This manifested with urine leak after a period of acute tubular necrosis. The graft was salvaged with an augment bladder flap to the lower calyces of the graft.

for ureteral strictures. Careful stenting and drainage are essential (Fig. 153-2).

Infection

Urinary infection is a long-term and often delayed complication that largely reflects the status of bladder function and underlying urologic causes of renal failure (Herthelius and Oborn, 2007; Silva et al, 2010). The presence of hydronephrosis is often associated with pyelonephritis and worsening renal function (Chu et al, 2013). Routine assessment of bladder emptying, hydronephrosis, and occasionally use of a VCUG will usually identify the cause. If the patient is on CIC and no specific correctable cause is present, a strategy of prevention by way of prophylactic antibiotics and bladder irrigation may be effective. Aggressive management of bladder dysfunction, which should have been identified pretransplant, is essential to preserve graft function. If vesicoureteral reflux into the graft and infection with fever and altered renal function are present, correction of the reflux is warranted. Reflux in the absence of infection with normal bladder function may be observed with caution.

Reflux

Vesicoureteral reflux into the transplant is entirely distinct from routine reflux into an otherwise normal renal unit. Because this is a reimplanted ureter, the risk to renal function of an episode of pyelonephritis is greater in a transplanted kidney, and the patient is immunosuppressed (DeFoor et al, 2003; Coulthard and Keir, 2006). Routine evaluation for reflux after renal transplant has been my practice, even though not all patients were treated with surgery. Identification of this potential risk factor is useful for clinical decision making and ongoing risk assessment. If febrile UTIs occurred, the presence of transplant reflux justifies surgical correction with an open ureteral reimplantation (Hanevold et al, 1987). The risk of pyelonephritis in the graft is significant (Neuhaus et al, 1997; Ranchin et al, 2000; Barrero et al, 2007) and increases the potential for graft loss (Herthelius and Oborn, 2007) (Fig. 153-3). Identification of simultaneous bladder dysfunction is equally important (Casale et al, 2005), although this may not be correctable. In the setting of intermittent catheterization, any reflux should be corrected because these bladders will be chronically colonized. Reflux in the absence of infection and bladder dysfunction may be observed, and attempts made to improve any suggestion of bladder dysfunction. There are no data to suggest that low-grade sterile vesicoureteral reflux into a renal graft is harmful in children. Close

Figure 153-3. Graft function at 1 and 4 years in children with one or fewer and two or more urinary tract infections (UTIs). GFR, glomerular filtration rate. (From Herthelius M, Oborn H. Urinary tract infections and bladder dysfunction after renal transplantation in children. *J Urol* 2007;177:1883-6.)

observation for possible infection or deteriorating bladder function is warranted.

Surgical management of reflux into a transplanted ureter is never routine. The role of endoscopic therapy is limited and the few reports available suggest limited benefit, with resolution rates of 50% to 80% (Kitchens et al, 2006; Williams et al, 2008; Vemulakonda et al, 2010). This may be an option for asymptomatic reflux, but in the face of an episode of febrile UTI, the most certain definitive intervention is justified. There are few data as to relative efficacy of intravesical compared with extravascular methods (Krishnan et al, 2006), but my preference is intravesical, often with use of extravascular mobilization. A transtrigonal technique is effective if the contralateral native ureter can be avoided. Otherwise, an advancement or Politano-Leadbetter technique may be used. Ureteral stenting is advisable.

Hydronephrosis and Obstruction

A frequent urologic complication in pediatric renal transplant is hydronephrosis, and intervention for ureteral obstruction may be needed in as many as 8% of transplants (Shokeir et al, 2005; Smith et al, 2010; Chu et al, 2013). The presence of hydronephrosis necessitates careful evaluation and selective management to tailor appropriate treatment to the individual. The transplant kidney appears to be one of the rare situations in which obstruction may not be associated with hydronephrosis. This is uncommon and not well documented, but empirically it can occur. More commonly, obstruction is heralded by increasing renal dysfunction with a rising creatinine. Hydronephrosis is identified on ultrasonography or delayed drainage on MAG3 renal scan. More than half of obstructions in a recent series occurred within the first 100 days post-transplant (Smith et al, 2010). In the setting of normal prior bladder function, this pattern indicates ureteral obstruction until proven otherwise. If bladder dysfunction is known to be present, then both factors must be evaluated and managed because obstruction is more frequent in patients with bladder dysfunction, particularly posterior urethral valves (Smith et al, 2010) (Fig. 153-4).

In the setting of a rising creatinine level and hydronephrosis, obstruction and rejection may be intermingled. If the hydronephrosis is mild and there are other signs of rejection, the most

Figure 153-4. Obstruction-free survival in pediatric renal transplant patients with and without a history of posterior urethral valve (PUV). (From Smith KM, Windsperger A, Alanee S, et al. Risk factors and treatment success for ureteral obstruction after pediatric renal transplantation. *J Urol* 2010;183:317–22.)

efficient first step is biopsy (Khater and Khauli, 2012). If there is no clinical suggestion of rejection, ureteral stenting with or without a biopsy is the best first step. Diagnostic studies for obstruction in the transplant setting are not completely reliable; given the associated risks, I have adopted the approach of stenting to assess the impact on renal function. It has been in this setting, albeit rarely, that an acutely failing transplant with minimal or no hydronephrosis and no evidence of rejection has been stented with subsequent improvement in function. The more common situation is with moderate hydronephrosis and a rising creatinine level with some rejection on biopsy. If the graft is not failing rapidly, initial medical treatment of the rejection is justified, with stenting being reserved for lack of improvement. Whether obstruction increases the risk of rejection is unproven but empirically suggested. In that light, having a low threshold for stenting, which can provide a definitive diagnosis of functionally significant obstruction, is essential.

The source of ureteral obstruction is usually in the distal ureter, with stenosis at the reimplantation site (Martino et al, 2013), but may be anywhere along the ureter. In a recent analysis, neither ureteral implant method nor use of stents was a contributing factor to obstruction. However, the presence of bladder abnormalities, particularly resulting from posterior urethral valves, was a risk factor for post-transplant obstruction (Smith et al, 2010). Compression from a lymphocele or adenopathy from post-transplant lymphoproliferative disease (PTLD) are also possible causes (Dharmidharka et al, 2001; Buell et al, 2006). Definitive therapy is determined by the most likely cause. Focal ureteral narrowing on retrograde imaging may be effectively treated with balloon dilation and stenting for 4 to 6 weeks. Long-term stenting has been used in adult series with thermolabile nitinol stents, but whether this would be a satisfactory approach in children is uncertain (Bach et al, 2013). In recognition of the risk posed to the graft by obstruction, open definitive repair should not be delayed excessively (Smith et al, 2010). These procedures are never simple and may entail complex reconstruction using native ureter or bladder flaps (Kockelbergh et al, 1993). Avoiding use of nonurothelial segments, such as appendix (Corbetta et al, 2012), is advisable, although any of these methods may be needed. Pyeloureteral anastomosis can be an option if the native ureter remains and is healthy (Sandhu et al, 2012). All the principles of reoperative reconstruction must be adhered to for preservation of well-vascularized functional tissues.

Bladder Dysfunction

Bladder dysfunction may produce infection, but may also create an obstructive process that impairs renal graft function (Herthel

lius and Oborn, 2006; Van der Weide et al, 2006; Herthelius and Oborn, 2007; Nahas et al, 2008). Discriminating this from ureteral obstruction may not be simple, and on occasion has necessitated sequential diagnostic drainage steps. If a bladder catheter can be placed easily, then continued drainage for 1 to 2 weeks with reassessment of creatinine can usually enable identification of bladder dysfunction as the cause of graft dysfunction if the creatinine declines. If not, then combined stent and bladder drainage followed by a recheck of the creatinine is needed. It should be recognized that elements of bladder and ureteral dysfunction might contribute to graft failure. Both may need to be addressed. Treating bladder dysfunction involves measures to increase compliance using anticholinergics as well as instituting or enhancing an intermittent catheterization program. Bladder augmentation may also be needed, although only after aggressive medical management has been tried. When intermittent catheterization per urethra is difficult, creation of a continent stoma may be needed. Identification of these potential risks to graft function is best accomplished before the transplant whenever possible.

Stones

Nephrolithiasis in a pediatric renal transplant is uncommon, occurring in up to 5% of patients (Khositseth et al, 2004) but more likely to occur in less than 1% (Stravodimos et al, 2012); it is potentially dangerous for long-term graft survival. With appropriate management, stones were not seen to increase the risk of graft loss but were associated with more UTIs (Khositseth et al, 2004). There is a high incidence of bladder stones, approaching 50%, and several stones were caused by retained suture material in the bladder (Lipke et al, 2004). Detection of an asymptomatic stone on routine surveillance should prompt attempts at removal as well as a search for cause. Stone associated with renal graft dysfunction caused by obstruction or infection should be managed with urgent intervention to ensure drainage and prompt removal. All conventional means of stone management are appropriate in a renal graft but should be modulated by recognition of the potential balance of risk to the graft as well as relative efficacy of the various modalities. Selection of a modality that will have the highest likelihood of success with a single intervention is likely to be the best option in the long-term, even if this involves more complexity. A lower pole stone may be best managed with a percutaneous approach or ureteroscopic removal rather than extracorporeal shock wave lithotripsy, given the lower success of clearance of lower pole stones. These decisions should be individualized based on clinical presentation, location and size of the stone, and renal functional status.

KEY POINTS: COMPLICATIONS

- Common urologic complications for pediatric renal transplant include ureteral stenosis (6%), urinary leaks (3%), stones (2%), and clinically significant reflux (2%).
- Urine leaks are typically identified in the early postoperative period with increasing fluid from the wound drains.
- Urinary infection is a long-term and often delayed complication that largely reflects the status of bladder function.
- Vesicoureteral reflux into the transplant is entirely distinct from routine reflux; the risk to renal function of acute pyelonephritis is greater.
- In the setting of a rising creatinine level and hydronephrosis, obstruction and rejection may be intermingled.
- The source of ureteral obstruction is usually in the distal ureter, with stenosis at the reimplantation site.
- Bladder dysfunction may produce infection but may also create an obstructive process that impairs renal graft function.
- Nephrolithiasis is uncommon but may occur in up to 5% of patients.

SUMMARY

Preparation and management of the pediatric transplant patient, particularly with an underlying urologic condition, requires a thorough understanding of the patterns of bladder dysfunction and clear strategies for evaluation and treatment before transplant. Anticipating the needs and constraints of the transplant procedure and being involved in appropriate cases permits a smoother procedure and ongoing continuity of care by the pediatric urologist. Post-transplant monitoring should be aggressively expectant to identify pathologic processes before they have damaged renal graft function irreversibly. This takes a high index of suspicion and a clear sense of the patient's risk for these processes. A multidisciplinary collaboration among the pediatric nephrology, urology, and transplant surgical teams is critical to maximizing patient and graft survival.

GENERAL COMMENTS ON PEDIATRIC RENAL TRAUMA

The Pediatric Kidney: Traumatic Renal Injuries and Congenital Renal Anomalies

The pediatric kidney is believed to be more susceptible to trauma owing to a decrease in the physical renal protective mechanisms found in childhood. Specifically, in contrast with the adult, the pediatric kidney is protected by an immature, more pliable thoracic cage, weaker abdominal musculature, and less perirenal fat and it sits in a lower abdominal position. Whether the incidence of renal injury following blunt abdominal trauma is truly increased in the pediatric versus the adult patient population is controversial, with statistical evaluations revealing mixed results, and the question remains in play (Brown et al, 1998; Chopra et al, 2002; McAleer et al, 2002a; Heyns, 2004).

What is known, however, is that preexisting renal abnormalities (i.e., ureteropelvic junction [UPJ] obstruction, hydronephrosis, horseshoe kidney) are three- to fivefold more common in pediatric patients undergoing a screening computed tomography (CT) scan for trauma than in the adult population (Brown et al, 1998; Chopra et al, 2002; McAleer et al, 2002a; Heyns, 2004).

Classically, patients with a preexisting congenital renal abnormality present with a history of hematuria disproportionate to the severity of trauma. Although it has been hypothesized that a preexisting congenital genitourinary (GU) anomaly would be associated with a higher stage of renal injury, this has not been documented to be true, with the majority of the patients still sustaining only renal contusions or minor renal fracture (Chopra et al, 2002; McAleer et al, 2002a; Al-Qudah and Santucci, 2006).

Screening for Genitourinary Injuries: the Difference between Adult and Pediatric Patients

Two major clinical findings suggest the need to work up the adult for a possible GU injury following trauma: the presence of gross hematuria or of microscopic hematuria (>50 red blood cells/high-power field) with shock (systolic pressure <90 mm Hg). In adults, if physicians use only these two criteria to screen for a traumatic GU injury, they will find 98% of the clinically significant GU injuries following blunt trauma and 90% of GU injuries associated with penetrating trauma (Mee et al, 1989; Heyns, 2004; Santucci et al, 2004a). Indeed, in the adult population 30% of the patients presenting with trauma-induced gross hematuria and 10% of the

patients with microscopic hematuria associated with shock are found to have a radiologically definable GU injury (Mee et al, 1989; Heyns, 2004; Santucci et al, 2004a). In contrast, in children there is poor correlation relating the degree of hematuria to the presence of renal injuries. In fact some studies have found that two thirds of children sustaining a grade 2 or higher renal injury will have a completely normal urinalysis (Morey et al, 1996; Buckley and McAninch, 2004, 2006; Santucci et al, 2004a). The correlation of hypotension to the extent of GU injury is also highly problematic; specifically, the sympathetic tone in children is able to sustain a normal blood pressure despite significant blood loss. In point of fact, in children serial hemoglobin/hematocrit values will invariably demonstrate significant decreases before orthostatic hypotension develops (Quinlan and Gearhart, 1990). In essence, in the pediatric patient presenting with a history of trauma the assessment of gross hematuria and microscopic hematuria with shock is not adequate to determine whom to screen for GU injuries. However, if two additional factors are added as screening criteria—the mechanism of injury and the presence of associated injuries—over 98% of clinically significant GU injuries can be identified. Notably, one of these two additional factors, the presence of coexisting injuries (i.e., injuries to the thoracic contents, intra-abdominal organs, and/or orthopedic fractures of the ribs, spine, pelvis, or femur), will on its own identify slightly less than 90% of the pediatric patients with a clinically significant traumatic renal injury (Levy et al, 1993; Morey et al, 1996; Buckley and McAninch, 2004, 2006; Heyns, 2004; Sahin et al, 2004; Santucci et al, 2004a, 2004b). These four crucial screening criteria have been found to be highly reliable and cost-effective in determining which pediatric patients should be screened for a possible GU injury and are outlined in Box 154-1 (Mee and McAninch, 1989; Mee et al, 1989; Herschorn et al, 1991; Heyns, 2004; Santucci et al, 2004a, 2004b; Wu and Gaines, 2007; Bernard 2009; Buckley and McAninch, 2011; Bartley and Santucci, 2012).

RADIOGRAPHIC AND ENDOSCOPIC ASSESSMENT AND TREATMENT OF UPPER TRACT GENITOURINARY INJURIES

FAST: Focused Assessment with Sonography for Trauma

Because of its low cost, wide availability, and freedom from ionizing radiation, ultrasonography has become a major screening tool in pediatric level 1 trauma centers. Use of the FAST examination to

BOX 154-1 Indications for Radiographic Assessment of Pediatric Patient for Possible Genitourinary Injury

All penetrating abdominal/pelvic traumas
or

A history of blunt abdominal trauma that meets one of the four following criteria:

1. A significant deceleration or high-velocity accident, fall from greater than 10 feet, or strike to the abdomen or flank with a foreign object (e.g., football helmet, baseball bat, hockey stick)
2. Significant trauma that has resulted in injuries to the thoracic contents and/or intra-abdominal organs, and/or orthopedic fractures of the ribs, spine, pelvis, or femur
3. Gross hematuria
4. Microscopic hematuria (>50 RBC/HPF) associated with shock (systolic blood pressure <90 mm Hg)

HPF, high-power field; RBC, red blood cells.

detect renal injuries has a reported specificity range of 95% to 100% (the ability to diagnose true negatives—kidneys without a clinically significant traumatic injury). However, the sensitivity (the ability to diagnose true positives—kidneys with a clinically significant traumatic injury) is highly variable and extremely operator dependent, with published sensitivity results ranging widely from 22% to 96% (McGahan et al, 1999; Jang et al, 2004; Sirlin et al, 2004; Suthers et al, 2004; Nural et al, 2005; Lee et al, 2007; Bent et al, 2008; Tsui et al, 2012). The clinical usefulness of a FAST scan is best when combined with serial physical examinations. If both the initial FAST examination and subsequent serial physical examinations performed for a 24-hour time period are within normal limits, the combination of these findings will virtually rule out the presence of clinically significant renal and/or intra-abdominal injuries (McGahan et al, 1999; Jang et al, 2004; Sirlin et al, 2004; Suthers et al, 2004; Nural et al, 2005; Lee et al, 2007; Bent et al, 2008; Tsui et al, 2012).

Because of the high specificity (true negative evaluation) of FAST, this examination has been proven to be extremely valuable in evaluating the hemodynamically unstable patient in whom emergent nephrectomy may become imperative. A rapid ultrasound assessment with Doppler verification of good blood flow to an uninjured kidney can be immensely helpful when faced with the possibility of an emergent nephrectomy resulting from a renal hilar injury (Riccabonna et al, 2011).

Abdominal and Pelvic Computed Tomography

The patient's hemodynamic stability determines whether, when, and occasionally what type of imaging studies can be done. The most sensitive and specific radiologic test to rule out a GU injury is a triphasic abdominal and pelvic CT study (precontrast scan, followed by a CT scan taken 1 to 3 minutes after injection of contrast [1.5 to 2 mL/kg] and then a 10-minute delayed scan). However, because of concerns for radiation exposure in children, a single-phase abdominal and pelvic CT study, with the scan taken within 5 minutes of injection of contrast, has clinically supplanted the triphasic CT study (Mee et al, 1989; Stein et al, 1994; Morey et al, 1996; Brown et al, 2001; Buckley and McAninch, 2004, 2006, 2011; Heyns, 2004; Santucci et al, 2004b; Al-Qudah and Santucci, 2006; Lee et al, 2007; Hardee et al, 2013). Although the single-phase CT study is beneficial in determining renal perfusion and the presence of major renal fractures, it is frequently unable to accurately determine the presence of perinephric fluid extravasation and will miss the majority of the isolated ureteral injuries (Boone et al, 1993; Hardee et al, 2013). Because of this fact I personally recommend that a delayed CT image be obtained 10 to 15 minutes

TABLE 154-1 Grading of Renal Injuries

GRADE OF RENAL INJURY	DESCRIPTION
1	Renal contusion or subcapsular hematoma
2	Less than 1-cm parenchymal laceration, all renal fragments viable, no urinary extravasation
3	Greater than 1-cm parenchymal laceration, includes renal segmental injuries resulting in devitalized fragments, no urinary extravasation
4	Laceration extending into the collecting system, includes renal segmental injuries resulting in devitalized fragments, urinary extravasation is present. Grade 4 includes shattered kidney, renal pelvic lacerations, and complete ureteropelvic junction disruption.
5	Injury to the main renal vasculature: major renal vessel laceration or avulsion resulting in uncontrollable hemorrhage or renal thrombosis of the major renal vessels

From Buckley JC, McAninch JW. Revision of current American Association for the Surgery of Trauma renal injury grading system. *J Trauma* 2011; 70:35–7.

following injection of contrast on all patients with a grade 3 or higher renal injury.

Radiologic Assessment of the Clinically Unstable Patient

In the clinically unstable patient requiring emergent laparotomy, once the patient is stabilized in the operating room single-shot intravenous pyelography (IVP) (2 mL/kg intravenous bolus of contrast) is performed with the x-ray taken 10 to 15 minutes following injection. Alternatively, if readily available an intraoperative renal ultrasound may be beneficial if exploration for an expanding retroperitoneal hematoma is considered. I would caution the reader regarding the quality of the single-shot IVP; this study is frequently a suboptimal examination with poor excretion/visualization of contrast because of the patient's clinical status. The chief benefit of the single-shot IVP or intraoperative renal ultrasound is to detect a normally functioning contralateral kidney (ultrasound should show good renal blood flow) if unilateral nephrectomy is a consideration. As an alternative to the single-shot IVP or intraoperative renal ultrasound, the patient can be stabilized and a delayed abdominal and pelvic CT evaluation obtained. Definitive surgical repair of any GU injury is subsequently deferred for 12 to 24 hours (Azimuddin et al, 1997; Heyns, 2004; Riccabonna et al, 2011).

Renal Trauma Grading System (Revised 2011)

In 2011, Buckley and McAninch recommended revision of the classic 1989 renal organ injury scale. This revision was proposed to alleviate significant discrepancies that existed in the literature regarding the classification of high-grade (grades 4 and 5) renal injuries. Specifically of note is the moving of the "shattered kidney" into a grade 4 classification. The current classification of renal injuries based on these recommendations is outlined in Table 154-1, and Figures 154-1 through 154-5 provide examples (Dugi et al, 2010; Buckley and McAninch, 2011; Shenfeld and Gnessin, 2011).

Figure 154-1. Computed tomography (CT) images, acute and delayed, with grade 1 renal trauma. **A**, Acute CT image of grade 1 renal trauma. Note normal-appearing parenchyma. **B**, Acute CT image coronal reconstruction of grade 1 renal trauma. **C**, Two-hour delayed CT image of grade 1 renal trauma revealing renal contusion with delayed excretion of contrast in cortex of contused renal parenchyma. **D**, Two-hour delayed coronal reconstruction of CT grade 1 renal trauma revealing delayed excretion of contrast in cortex of contused renal parenchyma.

Management of Complications from Traumatic Renal Injuries

The need for endoscopic, invasive radiologic, or open surgical intervention is dependent upon the patient's hemodynamic stability and the stage of renal injury, with few if any hemodynamically stable patients with grade 1 to 3 injuries (grade 3 with all renal fragments viable) requiring interventional management. In contrast, in hemodynamically stable patients with grade 3 to 5 renal injuries (grade 3 with devitalized fragments) intervention will be necessary for persistent or delayed bleeding in approximately 25% and intervention for symptomatic urinomas in approximately 15%. Surgical exploration to control complications not amenable to nonoperative techniques will occur in approximately 5% of patients. In essence, conservative management of hemodynamically stabilized patients with isolated grade 3 to 5 renal injuries will save approximately 95% of the patients an open surgical intervention (Husmann and Morris, 1990; Husmann et al, 1993b; El Khader et al, 1998; Bozeman et al, 2004; Buckley and McAninch, 2004, 2006; El-Sherbiny et al, 2004; Heyns, 2004; Santucci et al, 2004b; Broghammer et al, 2006, 2007; Henderson et al, 2007; Shariat et al,

2008; Cannon et al, 2008; Brewer et al, 2009; Umbreit et al, 2009; Eassa et al, 2010).

It is noteworthy that three classic CT findings are indicative that interventional therapy may become necessary (Cannon et al, 2008; Dugi et al, 2010; Bartley and Santucci, 2012). One is medial extravasation of contrast. This finding brings forth the concern for renal pedicle injury, UPJ disruption, or rupture of the renal pelvis. The latter two are considered in the differential diagnosis if there is medial extravasation of contrast associated with functioning renal parenchyma and no contrast is seen in the ipsilateral distal ureter. If there is medial extravasation of contrast, little to no functioning renal parenchyma, and a medial perinephric hematoma, and especially if there was intravascular contrast extravasation, concern for a renal pedicle injury arises. The finding of medial extravasation of contrast is no small matter, with approximately 75% of patients requiring either endoscopic, percutaneous, or open intervention. Second, a finding of lateral extravasation of contrast with no distal ureter visualized should generate a concern for ureteral injury and will either prompt the physician to obtain delayed radiographic images or prompt the need for cystoscopy and a retrograde pyelogram. Third, a perinephric hematoma of greater

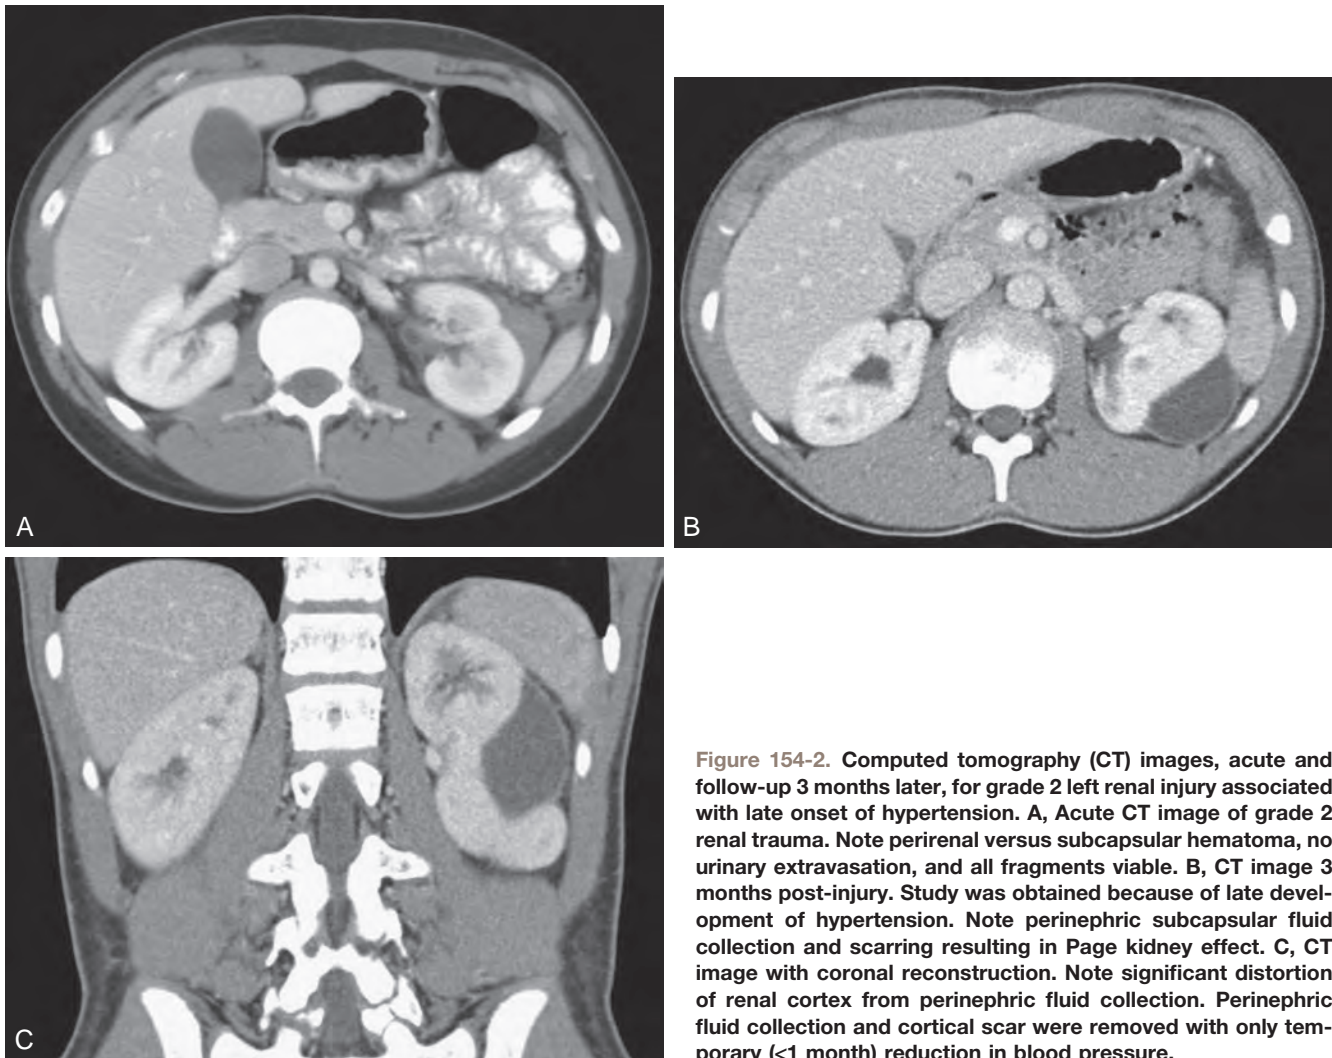

Figure 154-2. Computed tomography (CT) images, acute and follow-up 3 months later, for grade 2 left renal injury associated with late onset of hypertension. **A**, Acute CT image of grade 2 renal trauma. Note perirenal versus subcapsular hematoma, no urinary extravasation, and all fragments viable. **B**, CT image 3 months post-injury. Study was obtained because of late development of hypertension. Note perinephric subcapsular fluid collection and scarring resulting in Page kidney effect. **C**, CT image with coronal reconstruction. Note significant distortion of renal cortex from perinephric fluid collection. Perinephric fluid collection and cortical scar were removed with only temporary (<1 month) reduction in blood pressure.

than 2.5 cm, if in a lateral location, will usually be associated with persistent renal cortical bleeding that will require angiographic embolization. It is noteworthy that, if a hematoma of this size is medially located, concern for a major renal hilar injury that can result in sudden hemodynamic instability of the patient should be entertained (Nuss et al, 2009; Charbit et al, 2011).

Once the diagnosis of a traumatic renal injury is made, five possible complications can arise that may need to be addressed: (1) urinary extravasation, (2) an infected urinoma/perinephric abscess, (3) persistent or delayed renal hemorrhage, (4) hypertension, and (5) post-traumatic chronic pain syndrome.

Indications for and Use of Arteriography: Management of Persistent/Delayed Hemorrhage and Persistent Urinoma

Approximately 25% of patients with grade 3 to 5 renal trauma, managed in a nonoperative fashion, will develop persistent or secondary (delayed) hemorrhage (Wessells et al, 1997b; Dinkel et al, 2002; Goffette and Laterre, 2002; Kansas et al, 2004; Sofocleous et al, 2005; Al-Qudah and Santucci, 2006; Hotaling et al, 2011; Lin et al, 2013). Classically, delayed hemorrhage develops 5 to 14 days post-injury but may occur up to 1 month following the insult. Delayed hemorrhage usually arises from the development of arteriovenous fistulae or pseudoaneurysm malformations. In this scenario, the initial bleeding is tamponaded by the surrounding hematoma; as the hematoma resolves and liquefies, recurrent bleeding develops. Unlike the arteriovenous fistulae noted after

renal biopsy, for which a spontaneous resolution rate of greater than 70% is found, the vast majority of arteriovenous fistulae occurring after renal trauma will not spontaneously resolve, with almost all cases of delayed hemorrhage secondary to trauma requiring active intervention (Heyns and Van Vollenhoven, 1992; Dinkel et al, 2002; Goffette and Laterre, 2002; Heyns, 2004; Sofocleous et al, 2005; Al-Qudah and Santucci, 2006; Breyer et al, 2008; Umbreit et al, 2009; Eassa et al, 2010; Charbit et al, 2011; Hotaling et al, 2011). Angiographic embolization is currently the preferred treatment method for persistent or delayed bleeding with non-operative management protocols. Surgical exploration is reserved for embolization failure. Superselective angiographic embolization of isolated renal artery branches for persistent or secondary hemorrhage has a success rate approaching 80%. The percentage of salvaged renal function post-embolization varies depending upon the degree of the initial injury, but the median reported value is 30%. On occasion, angiographic embolization is used to treat persistent urinary fistulae. In this scenario, a functional transected fragment of a grade 4 renal injury is completely separated from the renal collecting system, and a persistent urinary fistula/urinoma has developed despite management by double-J stent and percutaneous nephrostomy tube placement. In these rare patients, selective angiographic embolization will resolve the urinary fistula by necrosing the isolated functional renal fragment (Pinto and Chimento, 1998; Heyns, 2004). Surgery if required following angiography is due to one of three problems: persistent or repetitive bleeding, postembolization abscess, or persistent urinary fistula from an isolated renal segment (Heyns and Van Vollenhoven, 1992;

Figure 154-3. Computed tomography (CT) images of grade 3 right renal trauma—acute, delayed, and at 3-month follow-up. A, Acute CT image of grade 3 renal trauma showing greater than 1-cm laceration of midrenal pole with perinephric hematoma. B, Acute CT image coronal reconstruction of grade 3 renal trauma, with possible devitalization of the entire lower pole of the kidney. C, Two-hour delayed CT image coronal reconstruction of grade 3 renal trauma, with no urinary extravasation noted and lower pole with questionable devitalization versus contusion. D, CT image coronal reconstruction 3 months after traumatic injury revealing parenchymal scarring at site of laceration with scarred but functional lower pole consistent with healed parenchyma following severe renal contusion. Scarring of lower pole was believed to have occurred with impoverished blood supply owing to severe contusion.

Dinkel et al, 2002; Goffette and Laterre, 2002; Heyns, 2004; Sofocleous et al, 2005; Al-Qudah and Santucci, 2006; Breyer et al, 2008; Brewer et al, 2009; Umbreit et al, 2009).

Postembolization syndrome is a well-recognized and self-limiting condition manifested by pyrexia (up to 40° C), flank pain, and an adynamic ileus. Symptoms will usually resolve within 96 hours after the embolization. Unlike angioinfarction for renal tumors, after which up to 60% of patients may develop postembolization syndrome, approximately 10% of patients develop this complication following angioinfarction after a traumatic injury. The decrease in the frequency of this syndrome following trauma is believed to be secondary to fewer pyrogens being released from the already partially necrotic tissue (Oesterling et al, 1986; Kehagias et al, 1998; Kalman and Varenhorst, 1999; Heyns, 2004; Mitra et al, 2004; Sofocleous et al, 2005; Breyer et al, 2008). The problem faced with persistent pyrexia following embolization is the need to rule out bacterial seeding of the necrotic tissue. It is therefore

mandatory in the presence of a febrile response following embolization to obtain blood and urine cultures. Consideration for a repeat CT scan with possible aspiration, culture, and drainage of the hematoma/urinoma should be given if symptoms persist for greater than 96 hours (Sofocleous et al, 2005; Breyer et al, 2008).

Indications for and Use of Retrograde Pyelography, Percutaneous Nephrostomy, and Perinephric Drain Placement: Diagnosis of Ureteropelvic Junction Disruptions, Renal Pelvis Lacerations, and Management of Symptomatic Urinomas and Perinephric Abscesses

Two indications exist for the use of retrograde pyelography following renal trauma: (1) the need to diagnose a partial/total ureteral disruption or renal pelvic laceration and (2) the need to

Figure 154-4. Computed tomography (CT) images of grade 3 renal trauma—patient unstable and no delayed images were performed. A and B, Acute CT images of grade 3 right renal trauma showing perinephric hematoma and multiple, less than 1-cm fractures, and association with either devitalized renal fragments, segmental renal artery occlusion, or severe renal contusion. C, Acute CT image showing no flow in distal right ureter. Patient required immediate surgical intervention as a result of acute respiratory difficulty secondary to multiple facial fractures with oral pharyngeal hematoma impairing airway. In addition, physical examination in emergency room revealed severe peritoneal irritation. Upon emergency surgery and after stabilization of patient, right retrograde pyelogram was obtained to rule out ureteral injury; no evidence of ureteral or collecting system injury was noted. Blood clot was seen to fill pelvis, and a ureteral stent was placed to aid drainage.

Figure 154-5. Acute and delayed images of grade 4 right renal injury. A and B, Acute computed tomography (CT) images of grade 4 renal trauma with perinephric hematoma, severe (>1 cm) fractures with devitalized renal segments, and urinary extravasation. C and D, Ten-minute delayed CT images revealing flow of contrast in ureter distal to injury, confirming patency of distal ureter. Patient was treated with observation only; no stent or drainage was necessary.

aid in the management of a symptomatic urinoma (Boone et al, 1993; Kawashima et al, 1997; Heyns, 2004; Santucci et al, 2004b). Concern for a ureteral injury usually arises when a CT scan reveals urinary extravasation and no ipsilateral distal ureter is seen. In the presence of these CT findings, a retrograde pyelogram is mandatory. This study is performed to either confirm or refute the diagnosis of a UPJ disruption or laceration of the renal pelvis, both of which require operative exploration and repair. If no evidence of these injuries is present I recommend that a ureteral stent be placed following the retrograde pyelogram. This recommendation is based on prior studies revealing that patients with trauma-induced urinary extravasation who have absence of contrast in the ipsilateral distal ureter are at a higher risk for developing a symptomatic urinoma if left unstented (Boone et al, 1993; Kawashima et al, 1997; Chopra et al, 2002; McAleer et al, 2002b; Smith et al, 2003; Santucci et al, 2004b; Al-Qudah and Santucci, 2006; Broghammer et al, 2006; Cannon et al, 2008; Umbreit et al, 2009; Eassa et al, 2010; Bartley and Santucci, 2012).

The second consideration for intervention with cystoscopy and retrograde pyelography is the presence of a symptomatic urinoma. Although most post-traumatic urinomas are asymptomatic and have a spontaneous resolution rate approaching 85%, urinomas will occasionally persist. Symptomatic urinomas will develop a classic triad of findings: ipsilateral flank pain, adynamic ileus, and a low-grade temperature. Management of these patients is by endoscopic intervention, with cystoscopy, retrograde pyelography, placement of a ureteral stent, urethral catheter drainage, and intravenous antibiotics. When a ureteral stent is placed in conjunction with temporary placement of a urethral catheter, greater than 90% of the symptomatic urinomas will resolve (Al-Ali and Al-Hajaj, 2001; Alsikafi et al, 2006; Umbreit et al, 2009). Classically, the urethral catheter is removed 3 to 5 days after the patient's clinical symptoms have abated. Intravenous antibiotics are discontinued and prophylactic antibiotics initiated at the time of urethral catheter removal. I remove the ureteral stent 4 to 6 weeks post-injury and will maintain oral prophylactic antibiotic coverage for 48 hours after stent removal. It should be noted that percutaneous nephrostomy drainage and internal stenting are equally efficacious for the treatment of symptomatic urinomas (Husmann and Morris, 1990; Husmann et al, 1993b; Philpott et al, 2003; Bozeman et al, 2004; Heyns, 2004; Keller et al, 2004; Al-Qudah and Santucci, 2006; Umbreit et al, 2009). The advantage of an internal stent is that it prevents possible dislodgment of the drainage tube and the need for external drainage devices. The two major disadvantages of internal drainage are that both stent placement and removal, in the pediatric patient population, require general anesthesia. In addition, the small-size ureteral stents (4 to 5 French) placed in young children may become blocked with blood clots from the dissolving hematoma, resulting in persistence of the urinoma (Husmann and Morris, 1990; Husmann et al, 1993b; Umbreit et al, 2009).

The development of a perinephric abscess after renal injury is extremely rare, occurring in less than 1% of renal injuries following blunt trauma and in 5% of renal injuries caused by penetrating renal trauma. It is more commonly seen in patients when there is a confluence of injuries—specifically, a devitalizing grade 3 to 5 renal injury in conjunction with either duodenal, pancreatic, or colonic injuries. This complication will also arise on occasion as a result of bacterial seeding from an infected venous line, from an ascending infection following bacterial colonization of a urethral catheter in conjunction with an indwelling ureteral stent, or following wound debridement (Husmann and Morris, 1990; Husmann et al, 1993b; Umbreit et al, 2009).

Symptoms of a perinephric abscess are intermittent febrile spikes, flank pain, persistent ileus, and elevated white blood cell count. These symptoms may exactly mimic those associated with an undrained symptomatic urinoma. In the absence of gas within the soft tissues, the differential diagnosis between a symptomatic urinoma and a perinephric abscess may be very difficult. I choose to treat all patients with these findings for a symptomatic urinoma and will resort to additional percutaneous drainage of the perineph-

ric fluid collection only if there is gas in the soft tissue at the time of initial diagnosis, or if the patient's febrile course persists after 72 hours of drainage with a ureteral stent and urethral catheter or nephrostomy tube in situ (Husmann and Morris, 1990; Husmann et al, 1993b; Al-Qudah and Santucci, 2006).

Follow-up Radiographic Imaging after Renal Trauma: the ALARA Concept (As Low As Reasonably Achievable)

Recommendations for follow-up renal imaging in the pediatric patient sustaining renal trauma are a balance of the physician's need to assess the percentage of residual functional renal tissue remaining and/or the need to confirm the resolution of the perinephric urinoma versus the concern for the future risk of radiation-induced malignancy (Alsikafi et al, 2006; Brenner and Hall, 2007; Malcolm et al, 2008; Shah and Platt, 2008; Eeg et al, 2009; Davis et al, 2010; Shirazi et al, 2010; Bukur et al, 2011; Shenfeld and Gnessin, 2011). The principle that radiation exposure for diagnostic and follow-up purposes should be kept to a minimum is known as ALARA—as low as reasonably achievable. This concept currently permeates all of pediatric practice and has greatly impacted both the initial trauma workup and follow-up recommendations for the post-traumatic injury phase. Presently, a CT scan is repeated in the acute post-traumatic phase only for patients who have specific symptoms: persistent or new onset of fever, persistent ileus, worsening flank pain, or persistent gross hematuria greater than 72 hours after the traumatic insult (Santucci et al, 2004b; Al-Qudah and Santucci, 2006; Buckley and McAninch, 2006; Bent et al, 2008; Malcolm et al, 2008; Davis et al, 2010; Shirazi et al, 2010; Bukur et al, 2011; Shenfeld and Gnessin, 2011). Although some authors have advocated performing a screening ultrasound in these circumstances, my experience in this situation is that the ultrasound is usually inconclusive, only serving to add to the financial cost of patient care and delay the inevitable CT scan. Based on my personal experience, I would preferentially recommend a CT scan for re-evaluation if the clinical circumstances suggest re-evaluation is necessary (Bent et al, 2008; Malcolm et al, 2008; Eeg et al, 2009; Tasian et al, 2010; Bukur et al, 2011).

Based on follow-up CT findings that renal scarring is essentially nonexistent after grade 1 to 2 renal injuries, no radiologic follow-up is recommended in this patient population. In contrast, approximately 50% to 60% of patients with grade 3 and 100% of patients with grades 4 and 5 renal injury will develop renal scars. For patients with grade 3 to 5 renal injuries, renal ultrasonography at 3 months is recommended for grade 3 lacerations where all fragments are viable. There is controversy regarding radiologic follow-up for grade 3 renal lacerations associated with devitalized fragments and for grade 4 and salvaged grade 5 renal injuries (Bent et al, 2008; Dunfee et al, 2008; Malcolm et al, 2008; Eeg et al, 2009; Umbreit et al, 2009; Davis et al, 2010; Shirazi et al, 2010; Bukur et al, 2011; Shenfeld and Gnessin, 2011). Although most authors recommend performing a repeat CT scan or magnetic resonance imaging (MRI) study at 3 months in this patient population, others advocate ultrasonography, with CT or MRI performed only in the presence of identifiable ultrasound abnormalities (Eeg et al, 2009). My personal experience is that a renal ultrasound will inevitably be abnormal following high-grade renal injuries, especially those associated with devitalized fragments, and the ultrasound will prompt additional evaluations. For cost-beneficial purposes, I will preferentially perform a CT evaluation, although consideration for an MRI study can be given in the older child when sedation/anesthesia would not be necessary. The delayed study (3 months post-injury) is done to document resolution of the urinary extravasation, assess the anatomy of the healed kidney, estimate percentage of renal function remaining, and rule out any occult complications (El-Sherbiny et al, 2004; Bent et al, 2008; Dunfee et al, 2008; Malcolm et al, 2008; Eeg et al, 2009; Umbreit et al, 2009; Davis et al, 2010; Shirazi et al, 2010; Tasian et al, 2010; Bukur et al, 2011; Shenfeld and Gnessin, 2011).

Serial dimercaptosuccinic acid (DMSA) scans obtained post-trauma have revealed that little, if any, renal parenchyma recovers function 1 week following injury. Therefore nuclear renography obtained any time within 1 week post-trauma results in a valid prognosis of renal function and can aid in the diagnosis of severe renal contusion versus a nonfunctional renal fragment following grade 3 kidneys with devitalized fragments or grade 4 and 5 injuries (see Fig. 154-3) (Wessells et al, 1997a; Moog et al, 2003). Currently, renal scans are obtained in two circumstances: when there is concern for long-term renal prognosis or in the presence of post-trauma-induced hypertension (Moog et al, 2003; Heyns, 2004). Classically, if the serum creatinine is normal, a differential renal function of greater than or equal to 30% demonstrates satisfactory ipsilateral renal function, which would prevent renal failure if the uninjured kidney is lost. In the presence of post-trauma-induced hypertension, captopril-enhanced mercaptoacetyl triglycine (MAG3) renography can be used to screen for trauma-induced renal vascular stenosis. Notably, the vast majority of patients with trauma-induced hypertension will have a kidney that has healed with a differential renal function of less than or equal to 20% and will be associated with poorly perfused renal parenchyma and not a major renal artery stenosis (Wessells et al, 1997a; Moog et al, 2003; Heyns, 2004; Keller et al, 2004; Santucci et al, 2004b; Chedid et al, 2006) (Fig. 154-6).

KEY POINTS: RADIOGRAPHIC AND ENDOSCOPIC ASSESSMENT AND TREATMENT OF PEDIATRIC UPPER TRACT GENITOURINARY INJURIES

- Radiographic assessment of the GU tract for a possible injury should occur following all penetrating abdominal trauma, as well as in blunt trauma victims who have one of four criteria: (1) a history of a significant deceleration or high-velocity injury; (2) significant trauma that has resulted in fractures of thoracic rib cage, spine, pelvis, or femur and bruising of the torso/perineum or signs of peritonitis; (3) gross hematuria; and (4) microscopic hematuria (>50 red blood cells/high-power field) associated with shock (systolic blood pressure <90 mm Hg).
- The two GU injuries most likely to be missed by a single-phase CT scan or single-shot IVP are perinephric fluid collections (urinomas) and isolated ureteral injuries. In patients with evidence of a grade 3 or higher renal injury, delayed excretory images are highly recommended.
- Three key findings noted on CT scan are suggestive that either endoscopic, interventional radiographic, or open surgical intervention will likely be necessary: medial extravasation of contrast, lateral extravasation of contrast with the ipsilateral distal ureter not visualized, and a perinephric hematoma of greater than 2.5 cm.
- Approximately 25% of patients with grade 3 to 4 renal trauma, managed in a nonoperative fashion, will develop persistent or secondary (delayed) hemorrhage. Superselective angioinfarction of the bleeding vessel is the preferred method to manage this complication.
- Most post-traumatic urinomas are asymptomatic and will spontaneously resolve. Approximately 15% of urinomas will be associated with continued flank pain, adynamic ileus, and/or low-grade temperature and require endoscopic or percutaneous management.
- Follow-up renal imaging is not recommended for grade 1 to 2 renal injuries and for grade 3 lacerations where all fragments are viable. Grade 3 renal lacerations associated with devitalized fragments and grade 4 and 5 renal injuries should have a repeat CT scan in the acute phase only if symptomatic; otherwise, a urinalysis and blood pressure check should be performed at 6 and 12 weeks post-injury and follow-up radiologic studies obtained at 12 weeks.

MANAGEMENT OF RENAL TRAUMA

Multiple studies have found that the nephrectomy rate in patients with traumatic renal injuries was higher with surgical exploration than with nonoperative management (Cass and Ireland, 1973; Cass et al, 1987; Kristjánsson and Pedersen, 1993; Hammer and Santucci, 2003; Keller et al, 2004; Broghammer et al, 2007). These papers suggested that hemorrhage from the severely injured kidney was held in check by a tamponade maintained by an intact Gerota fascia. Surgical exploration with disruption of the fascia resulted in uncontrollable renal bleeding and the need for emergent nephrectomy. Current studies reveal that this long-held hypothesis appears inaccurate. Specifically, with the enhanced ability of the CT scan to accurately stage renal injuries and with the development and application of trauma-related severity scores, multiple current studies reveal that the need for emergent nephrectomy during renal exploration is not due to intractable hemorrhage incited by the renal exploration; rather, emergent nephrectomy usually either is due to the severity of the initial renal injury or was performed in patients who had severe intraoperative hemodynamic instability as a result of multiple coexisting injuries. Nephrectomy in this latter situation was performed for expediency to save the hypothermic, coagulopathic, and clinically unstable patient (Husmann et al, 1993b; Wessells et al, 1997b; Gonzalez et al, 1999; Santucci and McAninch, 2001; Santucci et al, 2001, 2004b; Bozeman et al, 2004; Davis et al, 2006; Wright et al, 2006; Broghammer et al, 2007; Shariat et al, 2007, 2008; Umbreit et al, 2009).

Although all authorities agree that a clinically stable patient with an isolated renal injury should be managed in a nonoperative fashion, considerable controversy exists regarding the management of grade 3 or higher renal injuries when intra-abdominal injuries that mandate surgical exploration are found. There are three schools of thought in this controversy. One is that, provided no absolute indications for renal exploration are present, all renal trauma should be observed (Altman et al, 2000; Hammer and Santucci, 2003; Keller et al, 2004). A second is that renal exploration and renorrhaphy of a grade 3 or higher renal injury should be carried out if a laparotomy was to be performed for a coexisting intra-abdominal injury (especially if the stomach, duodenum, pancreas, or colon was injured) (Corriere et al, 1991; Husmann et al, 1993b; Heyns, 2004; Santucci et al, 2004b; Umbreit et al, 2009). A third is that renal exploration can be excluded in patients with concurrent intra-abdominal injuries provided the trauma surgeon separates the site of the enteric injury from the urinary tract by omentum or other alternative tissue and places perioperative drains. It is hypothesized that the separation of the two sites of injury and the placement of drains will prevent breakdown of enteric repairs caused by leaking urine and/or help prevent the development of urinary tract complications by removal of excess contaminating bacteria or pancreatic enzymes from the site of GU injury (Husmann et al, 1993b; Wessells and McAninch, 1996; Matthews et al, 1997; El Khader et al, 1998; Santucci et al, 2004b; Broghammer et al, 2007). Owing to the controversy, the major problem facing the urologist in the patient with traumatic renal injury is determining when to surgically intervene. The current recommendations on when to pursue operative intervention are based on three findings: the hemodynamic stability of the patient, an accurate radiographic staging of the renal trauma, and the presence of associated organ injury (Table 154-2) (Husmann and Morris, 1990; Husmann et al, 1993b; Wessells et al, 1997b; Heyns, 2004; Santucci et al, 2004b; Buckley and McAninch, 2006, 2011; Umbreit et al, 2009).

Nonoperative Therapy for Renal Trauma

The ideal candidate for nonoperative management is the hemodynamically stable patient sustaining either blunt or penetrating trauma, with or without associated intra-abdominal injuries, and having a grade 1 to 3 renal injury. Genitourinary complications in this subset of patients are minimal (Wessells et al, 1997b; Heyns, 2004; Santucci et al, 2004b; Charbit et al, 2011). Patients with grade 4 and 5 renal injuries who are hemodynamically stable, if

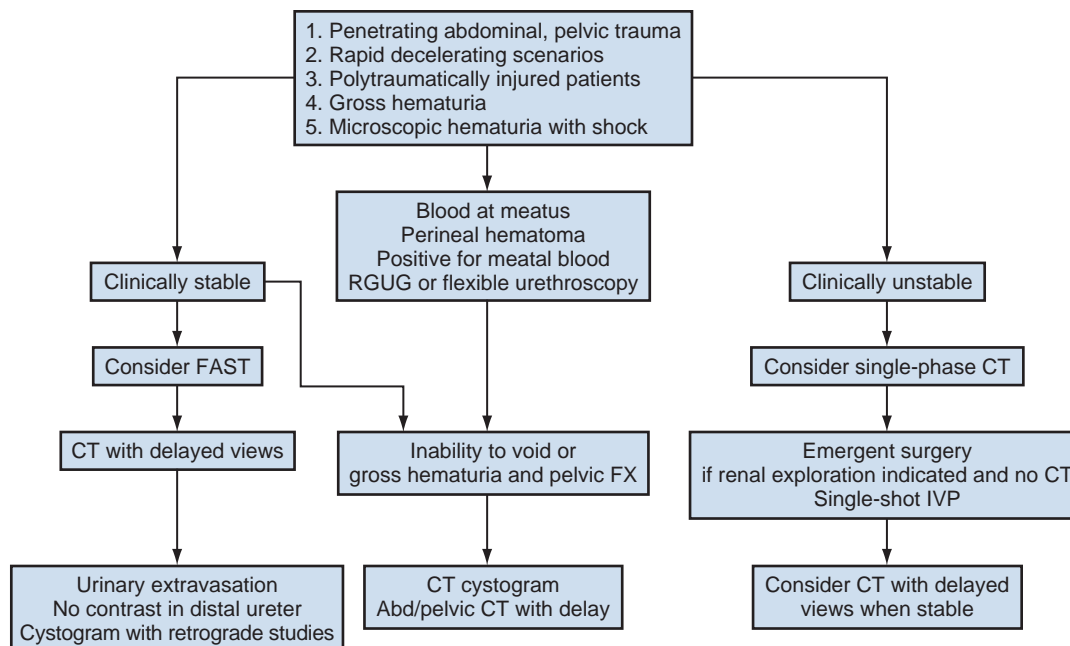

Figure 154-6. Recommended evaluation protocol for patients with a medical history or physical findings consistent with possible genitourinary injury. Abd, abdominal; CT, computed tomography; FAST, focused assessment with sonography for trauma; FX, fracture; IVP, intravenous pyelography; RGUG, retrograde urethrogram.

TABLE 154-2 Consensus Recommendations for Management of Renal Trauma

CLINICAL FINDINGS AND/OR GRADE OF RENAL INJURY	RECOMMENDED TREATMENT
Grade 1 or 2 renal injury irrespective of traumatic etiology*	Nonoperative
Isolated grade 3, grade 4, and hemodynamically stable grade 5 renal injuries	Nonoperative
Uncontrollable renal hemorrhage/vascular instability; occasionally grade 4 “shattered” kidneys and a high percentage of grade 5 injuries	Absolute requirement for surgical intervention
Persistent or delayed hemorrhage not responding to angiographic embolization	Absolute requirement for surgical intervention
Expanding pulsatile retroperitoneal mass found on surgical exploration for coexisting intra-abdominal injuries	Absolute requirement for surgical intervention (verify contralateral renal function prior to exploration)
Penetrating trauma, inadequate preoperative radiographic staging because of vascular instability of patient, retroperitoneal hemorrhage found on exploration	Retroperitoneal (renal) exploration recommended (verify contralateral renal function prior to exploration)
Blunt trauma; inadequate preoperative radiographic staging because of vascular instability of patient; no duodenal, pancreatic, or colonic injuries with retroperitoneal hemorrhage found on exploration	Observation—if FAST with bilateral blood flow. If no FAST obtained, consider intraoperative single-shot IVP/US with renal blood flow assessment or CT immediately following stabilization of patient
Blunt trauma; inadequate preoperative radiographic staging because of vascular instability of patient; duodenal, pancreatic, or colonic injuries with retroperitoneal hemorrhage found on exploration	Surgical interventions with renorrhaphy an option (verify contralateral renal function prior to exploration) or Drain intra-abdominal injuries. Observation—if FAST with bilateral blood flow. If no FAST obtained, consider intraoperative single-shot IVP/US with renal blood flow assessment or CT immediately following stabilization of patient
Blunt/penetrating trauma; radiographic screening studies reveal grade 3 renal injury with devitalized renal fragments, grade 4 or 5 renal injury, coexisting intra-abdominal injuries—especially duodenum, pancreas, and colon	Retroperitoneal (renal) exploration with renorrhaphy and repair recommended

CT, computed tomography; FAST, focused assessment with sonography for trauma; IVP, intravenous pyelography; US, ultrasound.

*Blunt or penetrating trauma.

they present with no other indications for surgical intervention, are also candidates for nonoperative treatment (Brewer et al, 2009). Even identification of a large segment of devitalized renal parenchyma, a perinephric hematoma greater than 2.5 cm in size, or a large medially or laterally placed urinoma is not an absolute contraindication for nonoperative management provided the patient is hemodynamically stable and the distal ureter is documented to be intact (see Fig. 154-5) (Umbreit et al, 2009; Buckley and McAninch, 2011; Charbit et al, 2011; Lin et al, 2013).

Nonoperative therapy consists of bed rest, close monitoring of vital signs and urine output, serial abdominal examinations, serial hemoglobin/hematocrit determinations, and transfusion as indicated (Heyns, 2004; Santucci et al, 2004b). In patients with a renal injury secondary to penetrating trauma who are on a nonoperative protocol, intravenous broad-spectrum antibiotics are recommended because of the risk of wound contamination. In renal injuries following blunt trauma, antibiotics may be considered if a large retroperitoneal hematoma, urinary extravasation, or extensive soft tissue injuries are present. The use of antibiotics following blunt renal trauma is advocated owing to the presence of indwelling urethral catheters and/or multiple intravascular catheters or superficial dermatologic abrasions, any of which could serve as a nidus for bacteremic colonization of the perinephric hematoma or urinoma (Husmann and Morris, 1990; Husmann et al, 1993b; Buckley and McAninch, 2004, 2006; Heyns, 2004; Kansas et al, 2004; Santucci et al, 2004b; Al-Qudah and Santucci, 2006; Umbreit et al, 2009; Charbit et al, 2011).

If the child becomes hemodynamically unstable or continues to have a decreasing hemoglobin/hematocrit despite transfusions, options of management usually involve a repeat CT evaluation. In an attempt to reduce radiation exposure, I will frequently skip a repeat CT scan and proceed directly to renal angiography with selective angioinfarction of the bleeding site. Similarly, in the patient with a known urinoma who has persistent fever, ileus, or flank pain, the physician can consider proceeding directly to endoscopic management of the urinoma with confirmation of the persistent urine leak with a retrograde ureterogram at the time of stent placement (Umbreit et al, 2009; Bukur et al, 2011).

Ambulation is allowed as soon as gross hematuria has resolved. In patients with a grade 1 renal injury desiring to return to sporting activities, re-evaluation of the athlete and urinalysis 48 to 72 hours after the injury is recommended. Provided physical examination is normal and the hematuria has cleared, athletic activities can be resumed. In individuals with persistent symptoms and/or microhematuria follow-up can occur at weekly to biweekly intervals with clearance for participation in sports once the aforementioned criteria have been met. In patients with grades 2 to 5 renal injury, recommendations are for a 6-week hiatus from their athletic endeavors. At 6 weeks, a physical examination and urinalysis are obtained; if the physical examination is normal and hematuria has cleared, the patient is allowed to resume all activities. As noted previously, I do obtain a functional renal study—either a CT/MRI or nuclear renography—to assess for the extent of kidney function and resolution of the urinoma in all patients with grade 3 renal injury with devitalized fragments and those with grade 4 and 5 injuries at 3 months after the traumatic insult (Wessells et al, 1997b; Heyns, 2004; Kansas et al, 2004; Santucci et al, 2004b; Al-Qudah and Santucci, 2006; Buckley and McAninch, 2006; Broghammer et al, 2007; Bukur et al, 2011).

Operative Intervention for Renal Trauma

Absolute indications for renal exploration are hemodynamic instability attributable to a renal source, an expanding or pulsatile retroperitoneal hematoma found at the time of surgical intervention for intra-abdominal injuries, and inability to stop persistent or delayed hemorrhage by selective vascular embolization. Relative indications for retroperitoneal renal exploration are a history of vascular instability resulting in an inability to obtain adequate preoperative radiographic evaluations, where surgical exploration for intra-abdominal injuries reveals duodenal, pancreatic, or colonic

injuries to coexist with a retroperitoneal hematoma. It is important to note that a single-shot IVP or renal ultrasound with assessment of renal blood flow to verify contralateral renal function is required before renal exploration (see Table 154-2) (Heyns, 2004; Santucci et al, 2004b). In this latter situation or in patients with a known grade 3 or higher renal injury undergoing exploratory laparotomy for multiorgan injury, options are either retroperitoneal renal exploration with renorrhaphy or placement of intraperitoneal and retroperitoneal drains with separation of the urinary tract injury from adjacent enteric injuries by interposing omentum. **Although the surgeon can choose between these two options, he or she should be aware that the consensus opinion is that renal exploration and renorrhaphy are preferred** (Husmann et al, 1993b; Wessells et al, 1997b; Santucci and McAninch, 2001; Buckley and McAninch, 2004, 2006; Heyns, 2004; Santucci et al, 2004b; Umbreit et al, 2009).

Renal salvage by renorrhaphy or partial nephrectomy requires complete exposure of the injured kidney, debridement of nonviable tissue, suture ligation of bleeding arterial vessels, and repair of the collecting system injury. Defects in the renal parenchyma may be closed primarily with renal capsule. For larger defects, I prefer the placement of Gelfoam (Pfizer, New York, NY) and Surgicel (Ethicon, Somerville, NJ) packing into the parenchymal defect, with coverage or closure of the renal capsule defect using woven polyglycolic acid mesh. Alternatively, perinephric fat, omentum, or thrombin-soaked gel foam may be used to pack the parenchymal defect. Watertight closure of the collecting system is not always possible and may be inadvisable. If the renal pelvis or ureter is closed with excessive stretch, further devascularization, tissue sloughing, and delayed urinary leakage may occur. If a major violation of the urinary drainage system is present, placement of intraoperative ureteral stents or a nephrostomy tube should be considered. Adequate drainage of the perinephric area following repair is vital. In the presence of concurrent duodenal, pancreatic, and colonic injuries, interposition of omentum or peritoneum between the site of the major renal injury and the site of the coexisting intra-abdominal injury is strongly advised. Nephrectomy should be considered in irreparable grade 4 or 5 renal injuries and in the hemodynamically unstable patient with multiorgan trauma. A nephrectomy may need to be performed in this latter situation to reduce operative time and help control bleeding in the hypothermic and coagulopathic patient (Heyns, 2004; Santucci et al, 2004b; Davis et al, 2006; Wright et al, 2006; Broghammer et al, 2007; Shariat et al, 2008; Umbreit et al, 2009).

Renal Vascular Injuries

In terms of arterial renal blood flow, the kidney is an end organ; only rarely is collateral blood flow outside of the main renal arterial supply sufficient to maintain renal function. **In a patient sustaining renal arterial trauma, the clinical triad of hemodynamic instability, inadequate collateral blood flow, and warm ischemic time almost invariably results in the inability to salvage renal function** (Turner et al, 1983; Knudson et al, 2000; Heyns, 2004; Santucci et al, 2004a; Dozier et al, 2013). In fact, attempted repair of the renal vascular injury in these crucially ill patients with grade 5 renal trauma has been associated with high failure rates and poorer patient outcomes than immediate nephrectomy (Turner et al, 1983; Knudson et al, 2000; Dozier et al, 2013). Because of these findings, no attempt to repair injuries to segmental renal vessels should be considered and repair of the traumatically injured main renal artery is seldom, if ever, indicated when a normal contralateral kidney is present. In essence, reconstruction of the main renal artery following trauma is only a primary consideration in patients who are hemodynamically stable with an injury to a solitary kidney or in patients with bilateral renal arterial injuries (Turner et al, 1983; Knudson et al, 2000; Heyns, 2004; Santucci et al, 2004a; Buckley and McAninch, 2011; Dozier et al, 2013). The infrequent exception to this rule is the presence of an incomplete arterial injury where perfusion to the kidney has been maintained by flow of blood either through the partially occluded main renal artery or through collateral vessels.

KEY POINTS: RENAL TRAUMA

- The ability of the CT scan to accurately stage renal injuries, combined with the application of trauma-related severity scores, suggests that emergent nephrectomy at the time of surgical exploration is usually due to either surgical expediency in the unstable patient or preexisting vascular damage, but it is not the consequence of intractable hemorrhage incited by the renal exploration.
- Nonoperative management is preferred in the hemodynamically stable patient with a grade 1 or 2 renal injury resulting from either blunt or penetrating trauma with or without associated intra-abdominal injuries. It is also the preferred treatment modality in isolated grade 3, 4, and 5 renal injuries when the patient is hemodynamically stable.
- Identification of a urinoma is not a contraindication for nonoperative management, provided that the distal ureter is documented to be intact.
- Absolute indications for renal exploration following trauma are (1) hemodynamic instability resulting from renal bleeding, (2) an expanding or pulsatile retroperitoneal hematoma, or (3) inability to stop persistent or delayed hemorrhage by selective vascular embolization.
- There are two relative indications for renal exploration. The first is finding a retroperitoneal hematoma at the time of surgical exploration for intra-abdominal injuries in a patient with inadequate preoperative radiographic staging. A single-shot IVP or intraoperative renal ultrasound with documentation of renal blood flow to verify contralateral renal function is required before renal exploration. The second is CT-documented presence of a grade 3 or higher renal injury coexisting with intra-abdominal injuries that require abdominal exploration.

native (Wessells et al, 1997b; Moog et al, 2003; Heyns, 2004; Keller et al, 2004; Santucci et al, 2004b; Chedid et al, 2006; Myrianthefs et al, 2007). Descriptions of treatment of hypertension caused by a subcapsular hematoma or fibrosis by decortication of the Page kidney have been published; however, the long-term results of this surgical treatment modality are extremely controversial (see Fig. 154-2) (Heyns, 2004; Santucci et al, 2004b; Myrianthefs et al, 2007).

KEY POINTS: RENAL VASCULAR INJURIES AND TRAUMA-INDUCED RENAL HYPERTENSION

- In renal arterial trauma, the clinical triad of hemodynamic instability, inadequate collateral blood flow, and warm ischemic time almost invariably results in inability to salvage renal function. Therefore repair of the traumatically injured main renal artery is seldom, if ever, indicated when a normal contralateral kidney is present.
- Hypertension secondary to renovascular trauma will usually develop within 36 months following the injury. If sustained hypertension does develop, evaluation with a DMSA scan to determine differential renal function and radiographic studies (MRI or CT angiography) to rule out development of an arteriovenous fistula as the source of the hypertension should be performed. Hypertension found to be related to an arteriovenous malformation may be treated with angiographic embolization.
- The most common clinical finding in post-trauma-induced hypertension is a small poorly functioning kidney (<20% function) associated with pan-nephric scarring, with nephrectomy being the best treatment alternative.

Trauma-Induced Renal Vascular Hypertension

The most common causes of post-traumatic renal hypertension are invariably renin mediated secondary to renal ischemia. Ischemia typically develops from one of four etiologies: (1) a partial arterial stenosis, (2) complete obstruction of a segmental or main renal artery with an intact peripheral blood supply, (3) trauma-induced alteration in blood flow resulting from an arteriovenous malformation or pseudoaneurysm, or (4) on extremely rare occasions, compression of the renal parenchyma by hematoma/fibrosis/urinoma (Page kidney model). **The presence of hypertension immediately following the traumatic insult may be secondary to pain and may resolve with observation. Persistent hypertension 30 days postinjury or hypertension developing within 3 months of the injury could be due to a trauma-induced renal source and the diagnosis should be considered.** The incidence of trauma-induced hypertension after a grade 3 or higher renal injury is approximately 5% (Heyns, 2004; Santucci et al, 2004b; Al-Qudah and Santucci, 2006; Chedid et al, 2006; Henderson et al, 2007).

In patients with suspected traumatic hypertension, blood pressure is controlled with angiotensin-converting enzyme inhibitors. Also, evaluation with both nuclear renography to determine differential renal function and radiographic studies (MRI or CT angiography) to rule out an arteriovenous fistula or a pseudoaneurysm as the source of the hypertension should be performed. Hypertension resulting from a vascular malformation may be treated with angiographic embolization. If consideration for surgical intervention is entertained, renal vein renin sampling for split renin ratios should be considered. The latter is especially helpful in the presence of segmental renal scarring when partial nephrectomy is a consideration for surgical management. In this situation, hypertension proven to be related to segmental renal ischemia can be treated by partial nephrectomy. **The most common clinical finding in patients with post-traumatic hypertension is a small, poorly functioning kidney (<20% function) associated with pan-nephric scarring; nephrectomy is the best surgical alter-**

Trauma-Induced Chronic Flank Pain following Renal Injury

Chronic flank pain developing after traumatic renal injury is reported to occur in approximately 7% of patients following grade 3 or higher renal injuries. CT scans with delayed images and, occasionally, renograms using furosemide (Lasix) (Sanofi, Bridgewater, NJ) are warranted. Findings of renal lithiasis, UPJ obstruction, and persistent urinoma will occasionally be found. Unfortunately, the majority of patients will not have a clear etiology for their chronic pain syndrome. Treatment will usually involve pain management and, on rare occasions, nephrectomy. I would caution the surgeon that removal of the kidney does not necessarily correlate with resolution of the pain (Mogensen et al, 1980; Al-Qudah and Santucci, 2006).

Recommendations for Activities and Follow-up in Patients with a Solitary Kidney

The recommendations by the American Academy of Pediatrics are that all patients with a solitary kidney who desire to participate in contact sports should undergo individual physician assessment, with recommendations for participation based on the physician's findings. Most urologists are currently making their recommendations on the basis of the following facts. Contact sports are the third most common cause of renal injury in children (Table 154-3). However, the mean stage of traumatic renal injury occurring as a consequence of contact sports is lower than that of all other etiologic causes of traumatic renal injury in children. Specifically, the mean stage for renal injury following bicycle, motor cross, and dirt bike accidents is 2.7 ± 1.0 , that for all-terrain vehicle (ATV) accidents is 2.4 ± 1.3 , that for falls is 2.4 ± 1.2 , and that for motor vehicle collisions is 2.1 ± 1.0 compared with the severity of injuries caused by contact and miscellaneous sports, which is 1.7 ± 1.0 (Committee on Sports Medicine and Fitness, 2001; Gerstenbluth et al, 2002; McAleer et al, 2002a; Holmes et al, 2003; Johnson

TABLE 154-3 Incidence of Pediatric Renal Injury Related to Mechanism of Injury

MECHANISM OF RENAL INJURY	PERCENTAGE OF RENAL INJURIES CAUSED BY BLUNT TRAUMA IN A PEDIATRIC POPULATION
Motor vehicle collision (including motor vehicle vs. pedestrian)	45%
Bicycle accidents (including dirt bikes and motor cross)	17%
Contact sports	12%
All-terrain vehicle accident	10%
Sports—miscellaneous (sledding, skiing, snowboarding, horseback riding, rollerblading, etc.)	7%
Falls	6%
Abuse/assault	3%

Data from Emmanuel et al (1977), Amaral (1997), Gerstenbluth et al (2002), McAleer et al (2002b), Johnson et al (2005), Broghammer et al (2006), and Wu and Gaines (2007).

et al, 2005; Wu and Gaines, 2007; Brophy et al, 2008). The facts as noted have prompted most pediatric urologists to clear patients with one kidney for participation in organized contact sports, provided three baseline criteria are met: the remaining kidney has normal anatomy, it is in the normal anatomic position, and protective gear is worn. These facts have also resulted in the routine cautioning of parents and patients that the child with a solitary kidney should wear a seat belt or be restrained in a car seat at all times, and that ATV activities, motor cross, and dirt bike racing are associated with increased risk for renal injury and participation in these activities should be done with caution (Committee on Sports Medicine and Fitness, 2001; Gerstenbluth et al, 2002; McAleer et al, 2002a; Holmes et al, 2003; Johnson et al, 2005; Wu and Gaines, 2007; Brophy et al, 2008).

One of the major questions that arises in the families of patients undergoing an emergent nephrectomy for trauma is, "After this procedure, what is the risk that my child will need dialysis or a renal transplant because of the development of chronic renal failure?" This parental concern arises from the child's lifelong risk of other systemic illnesses (i.e., metabolic syndrome, hypertension, diabetes, nephrolithiasis, renal cell carcinoma, and hyperfiltration injury) and, as mentioned, of subsequent trauma to the remaining contralateral kidney. To answer this question, a recent review of data in the National Trauma Data Bank, the National Inpatient Sample database, and the U.S. Renal Data System as well as their university-based urban trauma center database was carried out by Dozier and associates (2013). Their findings revealed that loss of a kidney by trauma had played a role in 0.1% of patients with dialysis/transplant-dependent renal failure in the United States. Using these data, the estimated risk to an individual that a trauma nephrectomy would play a role in causing dialysis-dependent renal failure is 0.5% (Dozier et al, 2013). It is unknown if closer follow-up of patients to prevent the onset of metabolic syndrome and adequate treatment of hypertension or hyperfiltration injury would lessen this risk.

MANAGEMENT OF PREEXISTING HYDRONEPHROSIS AND URETEROPELVIC JUNCTION DISRUPTION

Disruption of the UPJ is most commonly caused by acceleration/deceleration injuries (falling from >10 feet) or by a sudden extreme

hyperextension of the trunk (pedestrian–motor vehicle accident, ejection injury associated with motor vehicle accident). The mechanism of injury is hypothesized to be a sudden displacement of the more mobile kidney associated with a relatively fixed ureter, with force vectors from the traumatic impact interacting at the UPJ (Boone et al, 1992; Chopra et al, 2002; McAleer et al, 2002a).

Although it has been reported that preexisting hydronephrosis or a congenital UPJ obstruction renders the patient more susceptible to a UPJ disruption, this is controversial. The vast majority of patients with a history of trauma and preexisting UPJ obstruction or hydronephrosis will be found to have a renal contusion or grade 1 renal injury on evaluation (Fig. 154-7). If the initial CT scan reveals poor renal function secondary to a thinned cortex from the preexisting obstruction, I will usually place a percutaneous nephrostomy tube for 4 weeks and reassess function with a renal scan. Repair is recommended for patients with a differential renal function of greater than 20%.

When urinary extravasation is seen, rupture of the renal pelvis or a major laceration extending through a thinned renal cortex into the collecting system (grade 3 renal injury) is the most common finding, not a UPJ disruption (Boone et al, 1993; Hall and Carpinito, 1994; Gschwend et al, 1995; Kattan, 2001; Chopra et al, 2002; McAleer et al, 2002a; Smith et al, 2003; Ashebu et al, 2004). The majority of patients sustaining a UPJ disruption will present with vascular instability, requiring emergent laparotomy with the patient unable to undergo preoperative imaging. Urinalysis on presentation will have some degree of hematuria in 70% of patients; however, 30% of patients with UPJ disruption will have a completely normal urinalysis. Emergent exploratory laparotomy for coexisting intra-abdominal injury is usually necessary, and exploration fails to reveal the presence of a retroperitoneal hematoma (Boone et al, 1993; Hall and Carpinito, 1994; Gschwend et al, 1995; Chopra et al, 2002; McAleer et al, 2002a; Smith et al, 2003; Ashebu et al, 2004; Al-Qudah and Santucci, 2006). Because of the frequent association of this injury with life-threatening trauma, the diagnosis of a UPJ disruption is delayed for greater than 36 hours in more than 50% of patients (Boone et al, 1993; Kattan, 2001; Chopra et al, 2002; McAleer et al, 2002a; Al-Qudah and Santucci, 2006). Patients will eventually come to attention because of CT abnormalities found during the workup of persistent postoperative fever, chronic flank pain, continued ileus, or sepsis (Boone et al, 1993; Kattan, 2001; Chopra et al, 2002; McAleer et al, 2002a; Al-Qudah and Santucci, 2006). Three classic findings on a triphasic CT scan are associated with UPJ disruption: (1) absence of parenchymal laceration, (2) medial extravasation of contrast in the perirenal and upper ureteral area, and (3) no visualization of the ipsilateral distal ureter (Boone et al, 1993; Kawashima et al, 1997; Kattan, 2001; Chopra et al, 2002; McAleer et al, 2002a; Al-Qudah and Santucci, 2006).

In children with preexisting hydronephrosis secondary to congenital hydronephrosis or a UPJ obstruction the site of the injury is almost invariably a major laceration through the thinned renal cortex (grade 3 renal injury) or laceration of the renal pelvis; rarely is disruption of the UPJ present. These patients should undergo a retrograde pyelogram to confirm continuity of the UPJ and then can be safely managed with either a percutaneous nephrostomy or double-J stent placement, with delayed pyeloplasty performed following stabilization of the patient (Husmann and Morris, 1990; Matthews et al, 1997; McAleer et al, 2002a; Smith et al, 2003; Dugi et al, 2010; Bartley and Santucci, 2012).

In patients with a disruption of the UPJ diagnosis can be delayed up to 12 weeks post-injury, which will significantly increase the risk of nephrectomy (Boone et al, 1993; Kattan, 2001; McAleer et al, 2002a; Smith et al, 2003; Kunkle et al, 2006; Pereira et al, 2010). In the clinically stable patient, when the diagnosis is made within 5 days after the traumatic insult, I prefer to proceed to immediate surgical repair with debridement of any devitalized tissue, spatulation and reanastomosis of the ureter over a stent, and placement of an intraoperative nephrostomy tube and retroperitoneal drain. Because the area of ureteral necrosis may extend for 2 to 3 cm,

mobilization and downward displacement of the kidney may be necessary to obtain a tension-free anastomosis (Boone et al, 1993; Kattan, 2001; McAleer et al, 2002a; Smith et al, 2003). In patients with a delayed diagnosis of 6 or more days, I prefer to place a nephrostomy tube and allow the patient and injury to stabilize for 12 weeks. Differential renal function is then obtained using a DMSA renal scan, and the length of the ureteral injury is ascertained by a combined antegrade and retrograde pyelogram. The combination of remaining renal function and the length of the surgical defect allow the surgeon to make the proper surgical plan. Surgical alternatives in this situation include primary ureteroureterostomy, ileal ureter, autotransplantation, and nephrectomy. Notably, at the time of delayed repair there is usually significant technical difficulty in mobilization of the kidney, renal pelvis, and blood vessels; thus the option of nephrectomy should always be discussed and may become necessary (Boone et al, 1993; Kattan, 2001; Heyns, 2004; Santucci et al, 2004b; Kunkle et al, 2006).

URETERAL TRAUMA

External Trauma Resulting in Ureteral Injury

In children, external trauma causing ureteral injuries is rare, occurring in less than 4% of penetrating traumas, and is reportable following blunt trauma (Velmahos and Degiannis, 1997; Velmahos and Demetriades, 2002; Hudolin and Hudolin, 2003; Kansas et al, 2004; Elliott and McAninch, 2006; Pereira et al, 2010). Ureteral injuries will be found in conjunction with other intraperitoneal organ injuries in 90% of the patients and coexisting with renal or bladder injuries in 10%. Because of the frequent presence of multiple organ injury, the mortality rate of a patient sustaining a ureteral injury from external trauma is in excess of 30% (Velmahos and Degiannis, 1997; Wessells et al, 1997b; Velmahos and Demetriades, 2002; Hudolin and Hudolin, 2003; Carver et al, 2004; Kansas et al, 2004; Elliott and McAninch, 2006).

Figure 154-7. Spectrum of ureteropelvic junction (UPJ) obstructions presenting after renal trauma. **A,** A 16-year-old girl with gross hematuria and grade 1 left renal injury after a low-speed (<10 mph) motor vehicle collision. **B,** A 14-year-old boy with gross hematuria after being struck in the right flank with a soccer ball. Computed tomography (CT) scan revealed grade 1 injury. Percutaneous nephrostomy was placed for 4 weeks with follow-up mercaptoacetyl triglycine (MAG3) scan as noted in **C.** **C,** MAG3 renal scan revealing 25% function of right kidney 4 weeks following percutaneous nephrostomy tube placement. UPJ repair was subsequently performed. **D,** A 14-year-old girl presented with gross hematuria after a fall from a horse. Percutaneous nephrostomy was placed for 4 weeks, a DMSA renal scan showed less than 6% function at the end of 4 weeks, and a left nephrectomy was performed.

Figure 154-7, cont'd E, A 15-year-old boy presented with gross hematuria following a fall while running in a cross-country race; findings were suggestive of left lower pole UPJ obstruction. F, Left retrograde pyelogram confirmed incomplete left duplication with left lower pole UPJ obstruction. G, A 14-year-old male presented with gross hematuria following a collision while playing hockey. CT scan revealed horseshoe kidney with severe right UPJ obstruction.

Ureteral injuries associated with external trauma will lack the presence of hematuria in up to two thirds of the patients; the diagnosis is usually made by a triphasic CT study obtained to evaluate penetrating trauma and/or to rule out a GU injury following high-velocity deceleration or impact trauma (Velmahos and Degiannis, 1997; Wessells et al, 1997b; Medina et al, 1998; Velmahos and Demetriades, 2002; Hudolin and Hudolin, 2003; Carver et al, 2004; Kansas et al, 2004; Elliott and McAninch, 2006). Gunshot wounds caused by a high-velocity missile (>350 m/sec) deserve special mention. The kinetic energy of a high-velocity bullet creates a surrounding energy wave 30 to 40 times the missile diameter (Al-Ali and Haddad, 1996; Perez-Brayfield et al, 2001; Hudolin and Hudolin, 2003; Carver et al, 2004; Santucci et al, 2004b). In addition, the missile will frequently yaw or tumble during penetration, and the combination of blast injury and missile tumbling results in extensive damage to the surrounding tissues at a significant distance from its path. Of concern regarding high-velocity gunshot wounds to the torso is that radiographic and/or surgical evaluation at the time of the assault may not reveal the presence of a GU injury (Al-Ali and Haddad, 1996; Medina et al, 1998; Perez-Brayfield et al, 2001; Hudolin and Hudolin, 2003; Carver et al, 2004; Santucci et al, 2004b; Kunkle et al, 2006; Siram et al, 2010). In some patients with a high-velocity injury, the renal pelvis and/or ureter will appear intact or perhaps only slightly contused at the time of the radiographic examination and/or surgical exploration. As the high-velocity blast injury matures,

necrosis of the ureter or portions of the renal pelvis may develop. The extent of the GU injury finally comes to attention as urinary extravasation develops owing to delayed necrosis. Classically, blast injuries to the urinary drainage system present as an increase in urine output from surgically placed drains 3 to 5 days after the injury (Al-Ali and Haddad, 1996; Medina et al, 1998; Perez-Brayfield et al, 2001; Hudolin and Hudolin, 2003; Santucci et al, 2004b; Carver et al, 2004; Kunkle et al, 2006).

Iatrogenic Ureteral Injuries following Open, Laparoscopic, and Endoscopic Procedures

The most common iatrogenic ureteral injury in the pediatric population is injury following ureteroscopy; even these are rare events with ureteral perforations occurring in less than 2% of all prepubertal ureteroscopic procedures (Schuster et al, 2002; Wu and Docimo, 2004; Minevich et al, 2005). Ureteral perforation following ureteroscopy can almost invariably be managed with endoscopic intervention with ureteral stenting, with or without nephrostomy tube placement. Long-term results following endoscopic management are excellent (Schuster et al, 2002; Wu and Docimo, 2004; Minevich et al, 2005).

Traumatic ureteral injuries following laparoscopy or open surgical procedures are relatively common in adults following gynecologic and vascular surgery; however, literature reports of iatrogenic

ureteral injuries following laparoscopic and open procedures in pediatric patients are extremely rare (Elliott and McAninch, 2006; Routh et al, 2009). The management of traumatic ureteral injuries revolves around the timing of diagnosis, with a delay in the diagnosis of 6 days or greater found in 50% to 60% of both pediatric and adult patients sustaining these types of injury (Elliott and McAninch, 2006; Routh et al, 2009).

If recognized at the time of surgery, surgical division of the ureter and/or partial ureteral excision should be managed based on the location and length of the ureteral injury. Options are ipsilateral ureteroureterostomy, ureteral reimplantation with or without a psoas hitch, trans-ureteroureterostomy (beware of placing the contralateral normal kidney at risk), or, on rare occasions, ureteral ligation with placement of a nephrostomy tube and planned reconstruction in the next 48 to 72 hours. Ureteral contusions secondary to a high-velocity gunshot wound or inadvertent ligation of the ureter should be treated by removal of any offending clip or ligature and placement of a ureteral stent for 6 to 8 weeks. Long-term (1- to 2-year) radiologic follow-up after removal of the stent or ureteral repair is necessary because ureteral strictures or ureteral fistulae form over time (Al-Ali and Haddad, 1996; Ghali et al, 1999; Elliott and McAninch, 2006; Routh et al, 2009).

Patients diagnosed with a ureteral injury more than 5 days after traumatic insult are classically managed by placement of a temporary percutaneous nephrostomy tube with or without a concurrent ureteral stent and are offered delayed definitive repair 12 weeks postinjury. Acute repair is not recommended by some authors because of the intense inflammatory response noted at the site of the injury, making the repair more difficult and likely to be unsuccessful (Al-Ali and Haddad, 1996; Ghali et al, 1999). Other authors have challenged this recommendation, stating that a trial of acute endoscopic management is worth the effort. These authors recognize that management of delayed ureteral injuries with endoscopic methods is associated with a 40% complication rate, usually with the development of complex obliterative ureteral strictures, but is worth an initial attempt. In contrast, the classic delayed open repair has a complication rate of less than 10% and an attempt with endoscopic management risks infection in what could be an unstable patient recovering from major trauma, may significantly hinder the patient's hospital course, may worsen the extent of the ureteral stricture, and only defers the inevitable need for surgical repair (Campbell et al, 1992; Selzman and Spirnak, 1996; Elliott and McAninch, 2006; Kunkle et al, 2006; Routh et al, 2009; Pereira et al, 2010; Siram et al, 2010). I manage these patients using a combined approach, with an initial attempt to place a ureteral stent with or without a nephrostomy tube. If I successfully bridge the area of injury with a ureteral stent, I remove the stent 6 to 8 weeks following the traumatic insult and reassess the upper tract for developing hydronephrosis and renal function using ultrasonography and MAG3 diuretic renography 6 weeks later. If progressive hydronephrosis is noted, temporary drainage of the upper tract with a nephrostomy tube is performed. Diagnostic radiographic studies to assess renal function and to assess the location and extent of stricture are subsequently performed a total of 12 weeks following stent removal. If I was unsuccessful in bridging the area of ureteral injury, I assess the patient approximately 12 weeks following the traumatic injury. Radiographic assessment at this time may employ a variety of modalities: antegrade and retrograde pyelography, nuclear renography to assess differential renal function, CT urography, and cystography.

The type of delayed ureteral repair to be used is based on the location and the extent of ureteral damage. Options include direct ureteral anastomosis to the renal pelvis, ureterocalycostomy, primary ureteroureterostomy, trans-ureteroureterostomy, ureteral reimplantation with or without a psoas hitch, ileal ureter, autotransplantation, and, occasionally, nephrectomy. I would caution that the use of trans-ureteroureterostomy places the contralateral uninjured kidney and ureter at risk. Based on this concern, I dislike trans-ureteroureterostomy as a surgical alternative in managing the difficult problems that arise following traumatic ureteral injuries (Elliott and McAninch, 2006; Routh et al, 2009).

KEY POINTS: TRAUMATIC URETEROPELVIC JUNCTION DISRUPTION AND URETERAL INJURIES

- In patients sustaining a UPJ disruption, 30% will have a completely normal urinalysis.
- Because of the frequent association of traumatic UPJ disruption with life-threatening trauma, the diagnosis of this injury is delayed for greater than 36 hours in more than 50% of patients. Patients will eventually come to attention owing to CT abnormalities found during the workup of persistent postoperative fever, chronic flank pain, continued ileus, or sepsis.
- Three classic findings on a triphasic CT scan are associated with UPJ disruption: (1) medial extravasation of contrast in the perirenal and upper ureteral area, (2) contrast extravasation in the absence of parenchymal lacerations, and (3) no visualization of the ipsilateral distal ureter.
- In the clinically stable patient, when the diagnosis of UPJ or ureteral disruption is made within 5 days after the traumatic insult, immediate surgical repair is the preferred treatment modality.
- In patients with a delayed diagnosis of UPJ or ureteral disruption made 6 or more days after the traumatic insult, placement of a nephrostomy tube, with or without a ureteral stent, with delayed repair at 12 weeks is preferred.
- The type of ureteral repair used is based on the location and extent of the ureteral injury.

TRAUMATIC BLADDER INJURIES

General Comments

The urinary bladder is well protected from external trauma by the bony confines of the pelvis. Because of the extensive pelvic protective mechanisms, when bladder injuries do occur they are frequently associated with multiorgan trauma, with an average of three coexisting organ injuries and a mortality rate of 20% (Carroll and McAninch, 1984). It is noteworthy that 80% of bladder injuries are associated with pelvic fractures, conversely, only 5% to 10% of pelvic fractures are associated with a bladder injury. Several studies, however, have found that screening for a bladder injury in patients with a pelvic fracture alone, or in patients with a pelvic fracture and microhematuria, is neither cost beneficial nor of high yield for clinically significant bladder injuries (Mokoena and Naidu, 1995; Cunningham et al, 1998; Iverson and Morey, 2001; Zacharias et al, 2012). Currently, absolute indications for bladder imaging following blunt abdominal trauma are limited to only two: (1) the presence of gross hematuria coexisting with a pelvic fracture or (2) inability to void. Relative indications for bladder imaging following blunt abdominal trauma are urinary clot retention, perineal hematoma, and a history of a prior bladder augmentation. Bladder imaging following penetrating trauma should be performed any time concern exists that the missile could have injured the bladder and/or if free abdominal fluid is found on the initial CT scan (Cunningham et al, 1998).

Differences between Adults and Children in Traumatic Bladder Injuries: Lacerations through the Anterior Bladder Neck

Traumatic bladder lacerations in children are approximately two times more likely to extend through the bladder neck compared with the same injury in an adult (Husmann et al, 1990; Boone et al, 1992; Koraitim, 1997, 1999; Chapple, 2000; Ashley and Husmann, 2007; Routh and Husmann, 2007). The clinical importance of this fact is significant. Specifically, management of a bladder neck laceration with either a suprapubic tube alone and/or urethral

catheter alone without coexisting repair of the bladder neck may result in the persistent extravasation of urine with the possible development of a pelvic urinoma/abscess or pelvic osteomyelitis and an increased risk of permanent urinary incontinence (Husmann et al, 1990; Boone et al, 1992; Koraitim, 1997, 1999; Chapple, 2000; Ashley and Husmann, 2007; Routh and Husmann, 2007). The diagnosis of a bladder neck injury should be suspected any time extravasation of contrast is noted and a competent bladder neck cannot be documented with radiographic studies. If concern for a bladder neck injury is present, the patient should undergo surgical exploration with opening of the bladder at the dome. Repair of the bladder neck should be by an intravesical approach with a multilayered closure. Great care should be taken not to dislodge the pelvic hematoma to help prevent blood loss. The surgeon should be aware that anterior bladder neck lacerations are frequently associated with urethral injuries, and retrograde urethrography or cystoscopy to rule out this possibility should be considered. If a bladder neck laceration is repaired, a voiding cystourethrogram (VCUG) is necessary at the time of catheter removal to adequately visualize the bladder neck and confirm healing (Husmann et al, 1990; Boone et al, 1992; Koraitim, 1997, 1999; Chapple, 2000; Ashley and Husmann, 2007; Routh and Husmann, 2007).

Diagnosis of Bladder Injuries

The diagnosis of a traumatic bladder injury should be assessed by either standard or CT cystography. Either modality is accurate provided adequate bladder distention occurs. In a child, the amount of contrast instilled within the bladder should, at a minimum, be equal to one half of the estimated bladder capacity for age (60 mL at birth and 30 mL for each year thereafter). Instillation of contrast can stop at the maximum of bladder capacity for age, a total of 300 mL, or if a bladder contraction occurs. I would discourage performing a CT cystogram by plugging the catheter and evaluating the bladder at the time of the initial CT scan. Frequently, the injured patient has oliguria secondary to hypovolemia, resulting in diminished urine output with inadequate filling of the bladder. In my experience, performance of a CT cystogram by plugging the catheter alone has led to missing the diagnosis of a traumatic bladder injury on multiple occasions (Husmann, 1996; Haas et al, 1999; Peng et al, 1999; Deck et al, 2001; Iverson and Morey, 2001).

Classification and Treatment of Traumatic Bladder Injuries

All patients with traumatic bladder lacerations, either extra- or intraperitoneal, should initially be treated with intravenous antibiotics, with oral antibiotic therapy continued for 48 hours following removal of bladder catheters. Extraperitoneal injuries are twice as common as intraperitoneal injuries and are almost invariably associated with a pelvic fracture. Classically, extraperitoneal bladder ruptures will have a starburst appearance on radiographic studies. In the presence of an extraperitoneal bladder injury, consideration for open surgical intervention should be given if: (1) a bony spicule is found to protrude into the bladder on CT evaluation, (2) concern for a bladder neck laceration is present, (3) the patient is to undergo internal fixation of a pelvic fracture, or (4) the patient is to undergo an exploratory laparotomy for other injuries. In these select circumstances prompt repair of both intra- and extravesical bladder injuries has been associated with fewer complications and improved patient outcomes (Kotkin and Koch, 1995; Husmann, 1996; Gomez et al, 2004; Ashley and Husmann, 2007; Deibert and Spencer, 2011; Deibert et al, 2012). Uncomplicated extraperitoneal bladder injuries may be managed with catheter drainage; management by an indwelling urethral catheter can be considered. The age and size of the patient plays a major role in determining if the individual can be managed by an indwelling urethral catheter. In my experience, a small-caliber urinary catheter placed in young children will frequently be occluded by blood clots, resulting in persistent urinary extravasation and

possible bacterial colonization of a pelvic hematoma, leading to pelvic abscess or osteomyelitis. Placement of a large-bore urethral catheter to allow better drainage is a concern in young boys secondary to the possibility of urethral trauma resulting in a urethral stricture; therefore a large-caliber suprapubic tube should be placed (Kotkin and Koch, 1995). Urinary drainage through the bladder catheter is maintained for 7 to 10 days, and a cystogram should be obtained to verify healing of the injury prior to catheter removal.

Intraperitoneal bladder injuries will initially appear as free fluid in the abdomen on a CT scan. Instillation of contrast in the bladder will result in extravasation of the contrast into the peritoneal cavity. Almost all intraperitoneal bladder ruptures occur at the dome of the bladder, the site of least support by the perivesical surrounding structures. Because these lacerations are usually large in size, the integrity of the bladder neck frequently cannot be assessed by radiographic means (Husmann, 1996). In intraperitoneal bladder injuries, open surgical repair of the laceration is the recommended treatment modality, with multivariate analysis after controlling for overall body injury score revealing a reduction of in-hospital mortality by approximately 50% (4.3% with urethral catheter drainage vs. 2.1% with open repair) (Deibert and Spencer, 2011; Deibert et al, 2012). Open repair will allow the surgeon to reduce from the confines of the bladder any herniating omentum or small bowel that can result in persistent urinary extravasation and allows careful intravesical inspection of the bladder neck at the time of surgical exploration. In all patients, a perivesical drain is placed and a large-bore urinary catheter is used to provide urinary drainage. In younger females and/or boys, persistent gross hematuria with clots may occlude small-caliber urethral catheters, and placement of a larger-bore suprapubic tube is usually merited. Urinary drainage for 7 to 10 days after injury should be provided and a cystogram obtained prior to catheter removal.

KEY POINTS: TRAUMATIC BLADDER INJURIES

- Absolute indications for bladder imaging following blunt abdominal trauma are currently limited to two: (1) the presence of gross hematuria coexisting with a pelvic fracture or (2) complaints of inability to void.
- Bladder imaging following penetrating trauma should be performed any time concern exists that a missile could have injured the bladder and/or if free abdominal fluid is found on the initial CT scan.
- Traumatic bladder lacerations in children are approximately two times more likely to extend through the bladder neck compared with the same injury in the adult.
- Failure to repair a bladder neck injury may result in the persistent extravasation of urine, with the possible development of a pelvic urinoma/abscess or osteomyelitis and increased risk of permanent urinary incontinence.
- Traumatic bladder injuries can be accurately diagnosed by either standard or CT cystography, provided adequate bladder distention occurs. In a child, the amount instilled within the bladder should, at a minimum, be equal to one half of the estimated bladder capacity for age.
- In the presence of an extraperitoneal bladder injury, consideration for open surgical intervention should be given if a bony spicule is found to protrude into the bladder on CT evaluation or if concern for a bladder neck laceration is present. If these two complications are not present, management by an indwelling urethral catheter can be considered.
- In intraperitoneal bladder injuries, open surgical repair of the laceration is the recommended treatment modality. This allows the surgeon to reduce any herniating omentum or small bowel from the confines of the bladder and allows careful intravesical inspection of the bladder neck at the time of surgical exploration.

URETHRAL INJURIES

Differences between Pediatric and Adult Patients in Urethral Injuries

Because of the immature pelvis and the relatively intra-abdominal position of the child's bladder, children with a posterior urethral injury will differ from adults with this injury in four ways. First, a pelvic fracture is more likely to be unstable and associated with a severely and permanently displaced prostatic urethra. Second, the severe displacement of the prostate off the pelvic floor makes a complete posterior urethral disruption more common in boys than in men. Third, concurrent bladder and urethral injuries may occur in up to 20% of pediatric patients, with coexisting anterior longitudinal tears through the bladder neck and sphincteric complex being twofold more common in children compared with adults. Fourth, in prepubertal girls, pelvic fractures are four times more likely to be associated with a urethral injury than in adult women (Husmann et al, 1990; Boone et al, 1992; Perry and Husmann, 1992; Koraitim, 1997, 1999, 2004; Chapple, 2000; Hemal et al, 2000; Ashley and Husmann, 2007; Routh and Husmann, 2007).

The clinical impact of these differences is noteworthy. Permanent displacement of the prostate off the pelvic floor results in an increased need for either a transpubic, transsymphyseal, or combined transpubic and perineal dissection for urethral reconstruction compared with the adult patient population. Hypothetically, the severe displacement of the prostate off of the pelvic floor raises concern that erectile dysfunction will be more common in children sustaining a urethral injury than in adults (Boone et al, 1993; Koraitim, 1997; Chapple, 2000; Basiri et al, 2002). There is also apprehension that permanent urinary incontinence may be more likely in children following this injury as a result of the increased risk of combined injuries to the posterior urethra, bladder neck, and sphincteric complex (Husmann et al, 1990; Boone et al, 1992; Perry and Husmann, 1992; Hemal et al, 2000; Rosenstein and Alsikafi, 2006; Ashley and Husmann, 2007; Routh and Husmann, 2007).

Initial Presentation of Urethral Injury

Consideration for a urethral injury should arise any time a patient presents with a history of direct trauma to the penis, vagina, perineum, or pelvis. Radiographic or cystoscopic evaluations to rule out this injury are mandatory in the following circumstances: (1) when the patient presents with the classic triad of perineal/penile hematoma, blood at the meatus/vaginal introitus, and inability to void; (2) when there is a pelvic fracture with one or more fractured pubic rami or symphyseal diastases; or (3) when radiographic findings are suggestive of a bladder neck injury (Chapple, 2000; Rosenstein and Alsikafi, 2006).

Association of Pelvic Fractures to Posterior Urethral Distraction Injuries

Approximately 5% of patients sustaining a pelvic fracture will have a urethral injury. The risk of a urethral injury following a pelvic fracture is directly related to the number of pubic rami fractures present, the degree of separation of the pubic symphysis, and the presence of a concurrent diastasis of the sacroiliac joint. A Malgaigne fracture—that is, a pelvic fracture that has disruption of the ischiopubic rami coexisting with diastasis of the sacroiliac joint—has the highest risk of urethral injury (Colapinto, 1980; Kricun, 1990; Koraitim et al, 1996; Koraitim, 1999, 2004; Kommu et al, 2007). In turn, the likelihood of a urethral injury following isolated pelvic fractures of the acetabulum, ilium, and sacrum that do not involve a fracture of a ramus or the separation of the pubic symphysis is essentially zero.

Diagnosis of Urethral Injuries

In males, a retrograde urethrogram (RGUG) is the diagnostic modality of choice to rule out the presence of a urethral injury. In the pre- and postpubertal female, findings suggestive of a urethral injury are frequently noted on a CT evaluation; however, I prefer to confirm the diagnosis by cystoscopy and vaginoscopy performed under general anesthesia (Husmann et al, 1990; Boone et al, 1992; Perry and Husmann, 1992; Venn et al, 1999; Rosenstein and Alsikafi, 2006).

When a urethral injury is found to coexist with a pelvic fracture, a concurrent rectal injury will be present in 15% of children. It used to be mandatory that a digital rectal examination (DRE) be performed in these children to assess for the presence of the concurrent rectal injury. Current studies, however, have revealed the DRE to be highly inaccurate for diagnosing either a displaced prostate or a rectal injury. The ability of the DRE to correctly diagnose the presence of these findings was less than 15%, with radiographic studies and endoscopy being far more specific and sensitive for such a diagnosis. The emergency medicine community has subsequently recommended that the DRE be abandoned in the evaluation of the traumatically injured patient under these circumstances (Shlamovitz et al, 2007a, 2007b). When a rectal injury is identified to coexist with a urethral disruption, treatment with a temporary diverting colostomy is mandatory to prevent the disastrous consequences of pelvic abscess, pelvic osteomyelitis, and necrotizing fasciitis that can accompany an unrecognized rectal injury.

General Comments Regarding Repair of Urethral Injuries: Immediate, Delayed, and Late Urethroplasty

In the early phase of the injury, the most important potential urologic complication is infection induced by bacterial contamination of the pelvic/perineal hematoma and extravasated urine. Immediate treatment of urethral injuries should include the administration of broad-spectrum antibiotics, assessment of the competence of the bladder neck, and the establishment of urinary drainage. Repair of the urethral injury may be immediate (primary realignment or sutured primary end-to-end anastomosis, less than 2 days post-injury); delayed (primary realignment or sutured end-to-end anastomosis, occurring 2 to 14 days following injury); or late (any type of repair occurring 3 months or more after injury) (Boone et al, 1992; Perry and Husmann, 1992; Venn et al, 1999; Rosenstein and Alsikafi, 2006; Ashley and Husmann, 2007; Routh and Husmann, 2007).

Anterior Urethral Injuries

Anterior urethral (including bulbar) injuries in children are usually iatrogenic, resulting from urethral instrumentation, circumcision, or injury occurring during the repair of a congenital anorectal malformation. If the anterior urethra was injured as a result of urethral instrumentation, acute management should be with antibiotic therapy followed by establishment of urethral continuity with catheter drainage. Preferably, a urethral catheter is placed by either radiologic or endoscopic techniques and maintained for 5 to 21 days depending on the extent of the injury (Maheshwari and Shah, 2005; Kommu et al, 2007). If urethral continuity cannot be established, alternative treatments include temporary suprapubic tube placement or vesicostomy. If a urethral or suprapubic catheter is placed, a VCUG is obtained at the time of anticipated removal. If no persistent urethral injury is noted, in infants I obtain a follow-up RGUG after 3 months; alternatively, in a child who is toilet trained, a flow rate with ultrasound residual urine is adequate for follow-up. If a permanent urethral stricture develops, I will usually defer definitive surgical repair until the child is older than 1 year of age, or, if the child is older than 1 year of

age, wait at least 3 months from the time of the injury (i.e., a late urethroplasty). The delay in the repair allows the stricture to clearly delineate the extent of the injury, allowing the physician to plan for the urethral reconstruction (Voelzke et al, 2012).

Three types of urethral injuries can result following a circumcision: meatal injury, loss of the distal urethra secondary to partial or complete glanular amputation, or the development of a urethrocuteaneous fistula owing to ischemic necrosis of the urethra (Gluckman et al, 1995; Baskin et al, 1997). The latter injury usually occurs either when the urethra was crushed by a circumcision clamp or when a cautery or a suture ligature was used to stop bleeding from a vessel that was overlying the urethra (Baskin et al, 1997). Immediate repair of the acutely traumatized anterior urethra can be technically difficult. When the meatus is injured, a formal meatoplasty should be performed to prevent meatal stenosis from developing. When the glans with distal urethra has been amputated, it may be reattached successfully using a direct spatulated suture anastomosis of the urethra and glans with urethral stenting, perioperative antibiotics, and a compressive dressing for immobilization of the glans. When a partial distal urethral injury has occurred without substantial glans loss, suture reapproximation of the meatus (i.e., a meatoplasty) can be performed. After healing, a delayed repair using hypospadias techniques may be used if necessary. Urethrocuteaneous fistulae are repaired using techniques similar to those used to close fistulae following a hypospadias repair; this surgery is usually delayed until the child is 6 to 9 months of age for technical reasons (Gluckman et al, 1995; Baskin et al, 1997).

I have had a number of children referred to me for repair of urethral injuries that occurred at the time of surgical correction of their congenital anorectal malformation. In my experience, this injury is usually due to one of two causes: no urethral catheter was in situ at the time of the rectal repair or the urethral catheter had been placed into the rectum through the urethral-rectal fistula. In these circumstances, the proximal penile or bulbar urethra is usually excised or partially avulsed at the time of rectal dissection. The injury is frequently identified when the child is unable to void following surgery or voids through the perineal wound. The importance of an appropriately placed urethral catheter at the time of anorectal repair cannot be understated. Initial placement of the catheter prior to repair of the anorectal malformation may be difficult, because the catheter hangs up at the site of the rectourethral fistula or inadvertently passes into the rectum. Placement of the catheter over a cystoscopically placed guidewire prior to the surgical repair of this congenital anomaly is frequently helpful. This allows easy identification of the urethra, and if the urethral catheter becomes exposed during the case, the problem is recognized immediately and can usually be primarily repaired with rare long-term consequences (Spence, 1954; Williams and Grant, 1969; McLorie et al, 1998; Hong et al, 2002).

Assessment of Urethral Stricture prior to Delayed Repair

At the time surgical reconstruction is considered, usually 3 months post-injury, an RGUG followed by a simultaneous RGUG and VCUG are the first three studies done. If a suprapubic catheterization or vesicostomy has been performed, a static cystogram is also done. A correctly performed RGUG will allow the physician to identify the location of the urethral stricture but may not allow the appropriate determination of stricture length, especially if an extremely tight bulbar or posterior urethral distraction injury is present. Proper interpretation of these three radiographic studies is essential for true estimation of the defect between the disrupted urethral ends. Without correct interpretation of the studies, the urethral defect may be underestimated (contrast filling of a urinoma cavity associated with an incompetent bladder neck) or overestimated (nonfilling of the normal urethra as a result of failure of the bladder neck to open with voiding). When contrast from the static cystogram is found in the posterior urethra, it arouses suspicion for a bladder neck injury and mandates further evaluation as outlined later. If the bladder neck is competent, I obtain a simultaneous RGUG and VCUG. Great care should be taken in

interpreting these films. More often than not, the pediatric patient will be unable to void and will fail to open the bladder neck. This results in nonvisualization of the proximal urethral segment and may cause a spurious estimation of a long distraction defect. If the posterior urethra fills with contrast on the static cystogram, this could be due to either a poorly felt or described detrusor contraction or an incompetent bladder neck. Because of the significant impact the latter has on the surgical prognosis, if contrast is seen in the posterior urethra, a video-urodynamic study is necessary. If the video-urodynamic study documents an incompetent bladder neck, or if the patient was unable to open the bladder neck to allow visualization of the posterior urethra during VCUG, I perform a simultaneous flexible cystoscopy and urethroscopy. Occasionally, in children, the physician may need to use flexible ureteroscopes for this procedure. This examination allows the physician to confirm the anatomic detail of the bladder neck and allows determination of the extent of the urethral stricture. Specifically, I will obtain anteroposterior and oblique pelvic films with the flexible scopes placed at the distraction margins; this allows the physician to see the extent and orientation of the distraction injury. Alternatively, a pelvic MRI with three-dimensional reconstruction can be obtained to evaluate the prostatic urethral dislocation and distal bulbar urethral position. The latter radiographic study lacks the ability to evaluate bladder neck competence. If cystoscopy and video-urodynamics demonstrate an incompetent bladder neck, I discuss with the patient and his or her family the options of urethral reconstruction with the possible result of chronic incontinence or, alternatively, the performance of a continent abdominal stoma (appendicovesicostomy) as first-line therapy (Ashley and Husmann, 2007; Routh and Husmann, 2007) (Fig. 154-8) (also see the section Mitrofanoff Principle for Bladder Neck Incompetence following Posterior Urethral Injuries).

Endoscopic Repair of the Urethral Injury: Immediate Endoscopic Realignment, Delayed Urethroplasty with Direct Internal Visual Urethrotomy, and Delayed Urethroplasty with "Cut to Light" Procedure

Immediate endoscopic realignment using guidewires and urethral catheters for either partial or complete anterior or posterior urethral disruptions has been recommended by some authors (Husmann et al, 1990, 1993a; Koch, 1995; Elliott and Barrett, 1997; Freitas Filho et al, 2003; Maheshwari and Shah, 2005; Rosenstein and Alsikafi, 2006; Hadjizacharia et al, 2008). I believe this technique is extremely reasonable for partial urethral injuries secondary to iatrogenic catheter-induced or endoscopically induced urethral injuries; however, in my hands endoscopic realignment for noniatrogenic urethral trauma has produced abysmal long-term results. Indeed, in my patient population, with noniatrogenic urethral trauma managed by this technique, intermittent catheterization or repeated serial visual internal urethrotomies to maintain urethral patency were necessary in greater than 90% of children during long-term follow-up (Husmann et al, 1990, 1993a; Boone et al, 1992). Because of my poor experience with urethral realignment in children with noniatrogenic traumatic urethral injuries, I have elected not to pursue this treatment modality in prepubertal patients. In the postpubertal patient who is clinically stable with a posterior urethral distraction injury and a competent bladder neck, I will make a limited attempt at endoscopic realignment. If the alignment cannot be established within 10 minutes, I abandon the procedure for placement of a suprapubic tube and a delayed repair. The time limitation is used in an attempt to limit the risk of bacterial colonization of the pelvic hematoma and the possible consequence of osteomyelitis (Husmann et al, 1990, 1993a; Koch, 1995; Elliott and Barrett, 1997; Freitas Filho et al, 2003; Maheshwari and Shah, 2005; Rosenstein and Alsikafi, 2006; Hadjizacharia et al, 2008; Nerli et al, 2008).

The "cut to light" procedure, or antegrade and retrograde urethroscopy with either endoscopic incision or laser ablation of the obliterative urethral stricture, received publicity in the late 1980s as

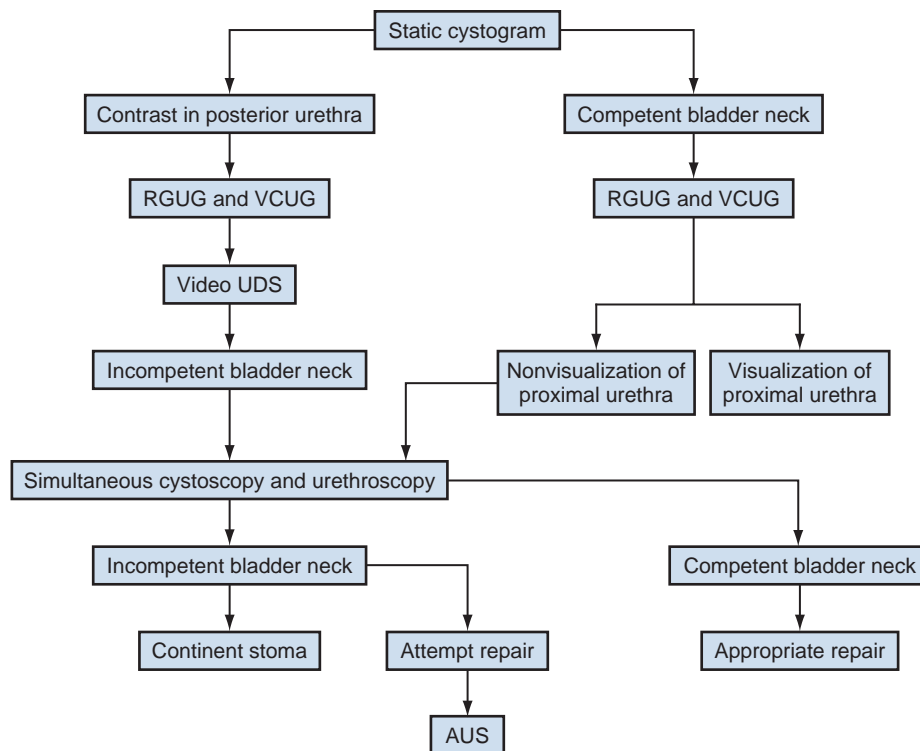

Figure 154-8. Workup of posterior urethral distraction injuries prior to delayed operative repair. AUS, artificial urethral sphincter; RGUG, retrograde urethrogram; UDS, urodynamic study; VCUG, voiding cystourethrogram.

a less invasive treatment for obliterative posterior urethral distraction injuries. Long-term follow-up has revealed a high recurrent stricture rate (>90%) with urethral patency being maintained only by daily use of intermittent catheterization. This finding has led most authorities in the field to abandon this treatment method (Tollefson et al, 2007).

Endoscopic urethrotomy for short (<1 cm) nonobliterative trauma-induced bulbar and penile urethral strictures is commonly performed for pediatric urethral stricture disease. Unfortunately, follow-up on these patients in adulthood is limited. Short-term follow-up of 1 year frequently reveals success rates as high as 75% to 100%; however, follow-up intervals of greater than 5 years reveal success decreasing into the 20% to 35% range, with some studies suggesting that long-term success can be doubled by repeating the urethrotomy at least one time. Repeating the urethrotomy more than one time does not appear to enhance its success and may, in fact, decrease the successful result of the eventual open urethral reconstruction (Roehrborn and McConnell, 1994; Albers et al, 1996; Duel et al, 1998; Hsiao et al, 2003; Hafez et al, 2005; Husmann and Rathbun, 2006).

Anastomotic Urethroplasty

The principles of anastomotic urethral reconstruction include complete excision of the scar tissue and a widely spatulated anastomosis with a tension-free epithelial-to-epithelial approximation associated with viable urethral margins. An anastomotic urethroplasty using either the perineal, transpubic, transsymphyseal, or combined approach has a reported success of greater than 90% in the pediatric patient population. The excellent outcome of this procedure verifies that the end-to-end anastomotic urethroplasty is the procedure of choice for distraction urethral injuries in both children and adults (Cooperberg et al, 2007; Tollefson et al, 2007; El-Sheikh et al, 2008). A direct end-to-end anastomosis of up to 2 cm may be performed in most children. Gaps of 3 cm or more

usually require partial or complete pubectomy or symphysiotomy with or without splitting the penile crura to accomplish the anastomosis (Boone et al, 1993; Chapple, 2000; Basiri et al, 2002; Koraitim, 2004; Park and McAninch, 2004; Cooperberg et al, 2007; El-Sheikh et al, 2008; Voelzke et al, 2012). As noted previously, because of the propensity of the child's prostatic urethra to be permanently displaced off the pelvic floor following a posterior urethral distraction injury, there will be a tendency for children to require either a partial pubectomy, symphysiotomy, or combined perineal and transpubic urethroplasty to complete the urethral reconstruction more often than would adults (Koraitim, 1997, 2004; Basiri et al, 2002; Park and McAninch, 2004; Ranjan et al, 2012; Voelzke et al, 2012).

Patch Urethroplasties: Flap versus Graft (One-, Two-, or Multistage Procedures)

Repair of traumatic urethral strictures of the bulbar, proximal, and penile urethra of greater than 3 to 4 cm in length in children is usually pursued using a one-stage flap procedure from the prepuce or penile shaft skin (Orandi procedure) or, if local skin is unavailable, a dorsal graft urethroplasty using a free-skin graft or buccal mucosa (Schreiter and Noll, 1989; Barbagli et al, 2004; Park and McAninch, 2004; Schulte-Baukloh et al, 2004; Dubey et al, 2005; Voelzke et al, 2012). I prefer to do a single-stage repair by approximating at least one side of the urethra and using the flap or graft on the opposing wall. If the defect is large enough that the flap or graft must be used in a circumferential manner (tube), I will opt for a two- or multistage approach. The use of a staged reconstruction is based on the realization that recurrent strictures are more likely to occur when any flap or graft is used in a circumferential manner (tube) as a single-stage procedure (Al-Ali and Al-Hajaj, 2001; Andrich and Mundy, 2001; El-Sherbiny et al, 2002; Dubey et al, 2003, 2005; Kessler et al, 2003; Manzoni et al, 2004;

Husmann and Rathbun, 2006; Voelzke et al, 2012). Staging the operation by performing a classic two-stage Johanson urethroplasty or, preferentially, a multistaged preputial flap or buccal graft urethroplasty allows the surgeon to verify flap/graft survival and provide time for neovascularity and the assessment of the urethral plate for possible hair-bearing skin prior to urethral closure. In general, the length of the urethral stricture, the availability of well-vascularized excess adjacent skin, and the health of the donor bed determine if I use a one-, two-, or multistage approach (Schreiter and Noll, 1989; Al-Ali and Al-Hajaj, 2001; Andrich and Mundy, 2001; El-Sherbiny et al, 2002; Dubey et al, 2003, 2005; Kessler et al, 2003; Manzoni et al, 2004; Schulte-Baukloh et al, 2004; Husmann and Rathbun, 2006; Ranjan et al, 2012; Voelzke et al, 2012).

Female Urethral Injuries

Urethral injuries in females are invariably associated with an unstable pelvic fracture and are usually caused by a disruption of the pubic symphysis with a longitudinal laceration extending through the bladder neck and into the urethra, or by dislocation of a bony fragment that lacerates the urethra, resulting in distraction of the two severed margins. Female urethral injuries may be quite insidious in nature and are associated with concurrent vaginal laceration in 75% and concurrent rectal injuries in 30% (Perry and Husmann, 1992; Venn et al, 1999; Chapple, 2000; Hemal et al, 2000). Blood at the vaginal introitus or the presence of a rectal injury in combination with a pelvic fracture should prompt the physician to consider a diagnosis of a female urethral injury. Urethroscopy and vaginoscopy should be considered mandatory in these individuals. If the patient is clinically stable, immediate end-to-end urethroplasty for avulsion distraction injuries, primary bladder neck repair, and repair of the longitudinal lacerated urethra over a urethral catheter should be performed. Concurrent repair of vaginal and rectal injuries (with a diverting colostomy) should be performed when indicated. Preliminary diversion with a suprapubic cystostomy without any treatment of the urethra will invariably result in either a urethral stricture, urinary fistula, or both. Delayed repairs of these injuries using a two-stage approach involving preliminary suprapubic cystostomy followed by a definitive reconstruction is less successful. Delayed urethral repair and establishment of urinary continence by bladder neck reconstruction, sling, or artificial urinary sphincter placement frequently results in incontinence, urethral erosion with fistula formation, or proximal urethral obliteration. Indeed, the need for urinary diversion or a continent abdominal stoma to manage complications of the female bladder neck and urethral injuries occurs in up to 30% of female pediatric patients (Perry and Husmann, 1992; Venn et al, 1999; Chapple, 2000; Hemal et al, 2000; Castera et al, 2001; Huang et al, 2003; Koraitim, 2004; Ashley and Husmann, 2007; Routh and Husmann, 2007).

Mitrofanoff Principle for Bladder Neck Incompetence following Posterior Urethral Injuries

In patients with bladder neck incompetence and concurrent urethral stricture disease, I have pursued two different treatment options. Initially, reconstruction of the bladder neck with reestablishment of urethral continuity is performed. If subsequent urinary incontinence persists, as it almost inevitably does, I proceed with placement of an artificial sphincter or bladder neck sling (Ashley and Husmann, 2007; Routh and Husmann, 2007). Alternatively, I may initially proceed with a continent catheterizable stoma using the Mitrofanoff principle, with no attempt to reestablish urethral continuity (Ashley and Husmann, 2007; Routh and Husmann, 2007). Indeed, personal experience with these two techniques has resulted in my preference for a continent stoma. Unfortunately, placement of an artificial urinary sphincter or sling around the bladder neck or urethra following bladder neck reconstruction and end-to-end urethroplasty is technically difficult and fraught with the risk of delayed urethral erosion (Ashley and Husmann, 2007).

Erectile Dysfunction and Urinary Incontinence following Urethral Injuries

For decades it was argued that immediate repair of posterior urethral disruption injuries by primary urethral anastomosis and/or primary urethral realignment was directly associated with an increased incidence of erectile dysfunction and urinary incontinence. Current studies have failed to reveal an association between the type of repair (immediate vs. late) and the incidence of erectile dysfunction and urinary incontinence. At this time, it is believed that the severity of the primary injury and not the initial treatment modality chosen is the cause of these complications (Husmann et al, 1990; Boone et al, 1992).

It should be noted that the incidence of erectile dysfunction is increased when total disruption of the urethra occurs and/or when the prostate is grossly dislocated, both of which are more common in children than in adults. The incidence of sexual dysfunction following this injury is correlated to the number of pubic rami fractured, the extent to which the pubic symphysis is distracted, and the length of the ensuing urethral stricture (Husmann et al, 1990; Boone et al, 1992; Koraitim, 1997, 1999; Chapple, 2000; Hemal et al, 2000). Long-term follow-up of children sustaining a posterior urethral disruption revealed that erectile dysfunction may occur in up to 70% when severe dislocation and injury to the apical prostatic urethra occurs, compared with a 30% incidence of erectile dysfunction when minimal dislocation of the pubic symphysis is present (Boone et al, 1992). Whether repair by an anastomotic urethroplasty increases the risk of erectile dysfunction is controversial (Das et al, 2004). Patients complaining about erectile dysfunction should undergo diagnostic testing to outline the etiology of the dysfunction. Although the etiology is usually neurogenic, vasculogenic, combined neurogenic and vasculogenic, and even psychogenic etiologies have all been found within this patient population, with therapy dictated by the diagnostic findings (Das et al, 2004; Feng et al, 2008; Tal et al, 2008).

Urinary incontinence following urethral injuries is almost invariably related to the presence of a concurrent bladder neck/urethral injury or is a consequence of pelvic or pudendal nerve damage resulting in denervation of the sphincteric complex (Husmann et al, 1990; Perry and Husmann, 1992; Koraitim, 1997; Chapple, 2000; Hemal et al, 2000; Ashley and Husmann, 2007; Kommu et al, 2007; Routh and Husmann, 2007).

PENILE INJURIES

Penile trauma in the pediatric patient population is most commonly iatrogenic and caused by circumcision. If excess penile skin is excised during circumcision, the majority of patients can be treated by wet-to-dry dressings and antibiotic ointment. Healing by secondary intention usually results in an excellent cosmetic appearance. If the penis is totally degloved, the penile shaft skin, if salvaged, can be defatted and replaced on the penis as a full-thickness skin graft (Gluckman et al, 1995; Baskin et al, 1997; El-Bahnasawy and El-Sherbiny, 2002).

Penile strangulation caused by a hair or thread is occasionally seen. In most cases it is hard to believe that this insult is purely accidental, and consideration should be given to a social services investigation for possible child abuse. The human hair-tie will result in the gradual onset of ischemia, with little or no discomfort to the child. If seen early, the glans or distal penis will be edematous, erythematous, and ulcerated. The constricting hair or thread may not be noticeable without careful inspection. Removal of the constricting agent at this stage usually results in no long-term complications. Unfortunately, if the child presents in a delayed fashion or if the original diagnosis is missed, the hair may continue to cut through the penis, causing damage to the neurovascular bundle, corporeal bodies, and urethra. Injuries range from loss of glanular sensation to the development of a urethrocutaneous fistula, and, in the extreme form, partial or complete penile amputation (El-Bahnasawy and El-Sherbiny, 2002; Radhakrishnan et al, 2002).

KEY POINTS: TRAUMATIC URETHRAL INJURIES

- A urethral injury should be ruled out in the following three circumstances: (1) if the classic triad of a perineal/penile hematoma, blood at the meatus/vaginal introitus, and inability to void is present; (2) if a pelvic fracture is associated with one or more fractured pubic rami and/or symphysis diastases; and (3) if radiographic findings are suggestive of a bladder neck injury.
- In a young girl with a pelvic fracture, if blood is noted at the vaginal introitus or if a concurrent rectal injury is present, urethral injury must be ruled out.
- Immediate treatment of urethral injuries should include the administration of broad-spectrum antibiotics, assessment of the competence of the bladder neck, and the establishment of urinary drainage.
- Short (<1 cm), nonobliterative bulbar and penile urethral strictures may be treated by a urethrotomy, with a success rate approaching 20% to 35%. Repeating the urethrotomy more than once does not appear to enhance its success and may, in fact, decrease the success of an open urethral reconstruction.
- Following a posterior urethral injury, the incidence of erectile dysfunction and urinary incontinence is directly related to the severity of the primary injury, that is, the severity of the prostatic dislocation, the concurrent presence of a bladder neck injury, or the presence of trauma-induced pelvic or pudendal nerve damage; it is not the result of the initial treatment modality chosen.

Domestic animal attack is the most severe form of penile trauma usually seen in childhood. These penile injuries are usually associated with significant tissue destruction and fraught with complications resulting from bacterial contamination. Treatment requires verification of a current tetanus vaccination and absence of rabies in the offending animal. The patient is treated with the liberal use of antibiotics, wound cleansing, and debridement and repair or reattachment of the penis as the injury would direct (El-Bahnasawy and El-Sherbiny, 2002; Radhakrishnan et al, 2002).

KEY POINTS: TRAUMATIC PENILE INJURIES

- During a circumcision, excision of excess penile skin in the vast majority of patients can be treated by wet- to-dry dressings and antibiotic ointment, with healing by secondary intention resulting in excellent cosmetic appearance.
- If during the circumcision the penis is totally degloved, the penile shaft skin, if salvaged, can be defatted and replaced back onto the penis as a full-thickness skin graft.
- Penile strangulation caused by a hair is occasionally seen, and consideration should be given to a social services investigation for possible child abuse.
- Domestic animal attack is the most severe form of penile trauma seen in childhood. Treatment requires verification of a current tetanus vaccination and absence of rabies in the offending pet. The patient is treated with the liberal use of antibiotics, wound cleansing, debridement, and repair or reattachment of the penis as the injury would direct.

SCROTAL, VULVAR, AND TESTICULAR TRAUMA

In the prepubertal and adolescent boy presenting with testicular/scrotal pain, the primary diagnosis should be testicular torsion until proven otherwise. Frequently, boys with testicular torsion will present with a trauma decoy, that is, a complaint of incidental scrotal trauma preceding the onset of testicular pain, with the patient's history masking the true diagnosis of torsion. **If clinical examination cannot clarify the diagnosis, scrotal ultrasonography is essential; any finding consistent with testicular torsion, hematocele, or irregular testicular outline mandates surgical exploration to rule out and/or repair a ruptured testis (Lee et al, 2008).**

In the pediatric patient, trauma to the scrotum or vulvar region is usually the result of athletic activities, an assault, or a fall. It is classically divided into the two categories of penetrating or blunt trauma. If the patient has sustained a penetrating scrotal or vulvar trauma, concern for associated injuries to the urethra and rectum exists (Husmann et al, 1993a; Lee et al, 2008). A history of vaginal or rectal penetrating injuries, hematuria or bloody rectal discharge, and the presence of blood staining/bruising in the scrotal, labial, or perineal area should prompt further evaluations for coexisting urethral and rectal injuries. In some situations, scrotal ultrasonography, pelvic CT, or MRI may be of significant benefit if the history is unclear, child abuse is suspected, and physical findings are worrisome. If sedation in the emergency room is inadequate in allowing the physician to perform a thorough physical examination of the genitalia, it may be necessary to bring the patient to the operative suite for general anesthesia. In all cases of penetrating trauma, a meticulous examination to determine the depth of penetration, along with cleansing and debridement of the wound, broad-spectrum antibiotics, and verification of an up-to-date tetanus immunization are employed.

155 Pediatric Urologic Oncology: Renal and Adrenal

Michael L. Ritchey, MD, and Robert C. Shamberger, MD

Neuroblastoma

Wilms Tumor

Other Renal Tumors

NEUROBLASTOMA

Neuroblastoma is the most common extracranial solid tumor of childhood. Regrettably, over half of the children have metastatic disease on presentation. Neuroblastoma is known to arise from cells of the neural crest that form the adrenal medulla and sympathetic ganglia. Tumors may occur anywhere along the sympathetic chain within the neck, thorax, retroperitoneum, or pelvis, or in the adrenal gland. Seventy-five percent arise in the retroperitoneum, 50% in the adrenal, and 25% in the paravertebral ganglia. The variety of locations where these tumors arise and the spectrum of their differentiation results in a wide range of clinical presentations and behaviors (Brodeur, 1991). These tumors can undergo spontaneous regression (Brodeur, 1991), differentiate to benign neoplasms, or exhibit extremely malignant behavior. Biologic factors have been defined that predict and explain much of the variance in behavior from one tumor to the next.

Epidemiology and Genetics

Incidence

Neuroblastoma accounts for 8% to 10% of all childhood cancers. In the United States, the annual incidence is 10 cases per 1 million live births. It is the most common malignant tumor of infancy. A recent review of 3666 children enrolled in the cooperative group trials of the Pediatric Oncology Group and the Children's Cancer Group showed a median age at diagnosis of 19 months (Brodeur and Maris, 2006). Thirty-six percent were infants, 89% were younger than 5 years, and 98% were diagnosed by 10 years of age.

Genetics

A number of familial cases have been reported, which are postulated to represent an autosomal dominant pattern of inheritance (Knudson and Strong, 1972a; Robertson et al, 1991). Although the median age at diagnosis of neuroblastoma is 19 months, in familial cases it is 9 months (Kushner et al, 1986). At least 20% of patients with familial neuroblastoma have bilateral adrenal or multifocal primary tumors, which are quite unusual in spontaneous cases. The risk for development of neuroblastoma in a sibling or offspring of a patient with neuroblastoma is less than 6% (Kushner et al, 1986). Linkage analysis in seven families with two or more first-degree

relatives affected with neuroblastoma identified a single interval at chromosome 16p12-13 with consistent linkage (Maris et al, 2002). This suggested that a hereditary neuroblastoma predisposition gene may be located at this site and may explain the familial cases. Subsequent studies in these familial cases, which account for less than 1% of patients with neuroblastoma, have identified *PHOX2B* and *ALK* as hereditary predisposition genes (Mosse et al, 2004, 2008).

Constitutional Chromosome Abnormalities

Numerous karyotypic abnormalities have been found in neuroblastoma, and these are recognized to have prognostic significance. These changes occur in the form of chromosomal deletions, translocations, and cytogenetic evidence of gene amplification. Aneuploidy of the tumor DNA, an abnormal number of copies of the normal 23 chromosomes, occurs in a significant number of cases (55%) and is a favorable prognostic indicator when compared with tumors that have a normal or tetraploid number (Kaneko et al, 1987). Amplification of the *MYCN* oncogene defined as greater than 10 copies of this gene is seen in roughly 20% to 25% of primary tumors and is an adverse prognostic indicator (Look et al, 1991; Muraji et al, 1993). It is present in 40% of patients with advanced stage disease but in only 5% to 10% of children with low-stage disease (Brodeur et al, 1984). It is associated with rapid tumor progression and poor outcome from treatment. These findings have been so striking that neuroblastoma was the first tumor in which the intensity of chemotherapy for a patient was determined not only by the stage and histology of the tumor, but by its "biologic markers," which were primarily chromosomal (Matthay et al, 1998).

Deletion of the short arm of chromosome 1 (1p) is found in 25% to 35% of neuroblastomas and is an adverse prognostic marker (Brodeur et al, 1992; Caron et al, 1996). The deletions are of various lengths, but, in a series of eight cases, a consensus deletion included the segment 1p36.1-2, suggesting that a tumor suppressor may be present in this region. Although the involved genes have not been identified conclusively, *CHD5* is a strong candidate for this role (Weith et al, 1989; Maris et al, 2007; Fujita et al, 2008). This deletion is present in 70% of advanced-stage neuroblastomas, and it has been demonstrated to be an independent prognostic factor (Attiyeh et al, 2005). There have been reports of constitutional abnormalities involving the short arm of chromosome 1 (Laureys et al, 1990). Recently, it has been demonstrated that loss of

Figure 155-1. A, Poorly differentiated neuroblastoma with a minimal-to-moderate amount of neuropil. B, Ganglioneuroblastoma with more than 50% of surface area occupied by schwannian stroma on left. Lobule contains ganglion cells, immature ganglion cells, and poorly differentiated neuroblasts; only minimal neuropil is present within lobule. (Courtesy Dr. Harry Kozakewich.)

heterozygosity (LOH) at 1p36 and Unb11q is independently associated with a worse outcome in patients with neuroblastoma (Attiey et al, 2005). (Unbalanced LOH implies LOH at markers on 11q with retention of 11p material, in contrast with *whole-chromosome* 11 LOH, wherein there is LOH at every marker along the chromosome.) Of note, although the 1p deletions are seen in conjunction with advanced stage and *N-MYC* amplification, the 11q deletions are rarely seen in tumors with *N-MYC* amplification but are associated with other high-risk features (Spitz et al, 2006). An additional genetic abnormality, gain of one to three copies of 17q, often the result of translocation with chromosomes 1 or 11, has been demonstrated to correlate with more aggressive tumors (Bown et al, 1999). The breakpoints vary, but the addition of a region from 17q22-qter is common, suggesting that genes replicated in this region provide an advantage (Schleiermacher et al, 2004). In multivariate analysis, gain of 17q was the most powerful prognostic factor, followed by the presence of stage 4 disease and deletion of 1p.

Embryology and Spontaneous Regression

In 1963, Beckwith and Perrin coined the term *in situ neuroblastoma* for small nodules of neuroblasts found incidentally within the adrenal gland that are histologically indistinguishable from neuroblastoma (Beckwith and Perrin, 1963). *In situ* neuroblastoma was found during postmortem examination in 1 of 224 infants younger than 3 months. This represents an incidence of approximately 40 to 45 times greater than that of clinical tumors, suggesting that these small tumors regress spontaneously in most cases. Subsequent studies have shown that these neuroblastic nodules are found in all fetuses studied and typically regress (Ikeda et al, 1981). Neuroblastoma identified by prenatal ultrasonography has also been shown to have a clinically favorable course (Ho et al, 1993).

The concept of *in situ* neuroblastoma has been used to support the argument that many neuroblastomas arise and regress spontaneously. This concept has been further supported by population-based studies in Quebec province and in Japan, where prospective screening of infants for neuroblastoma has been performed based on urinary catecholamine excretion. An increased number of children were identified with low-stage neuroblastoma, a higher frequency than present clinically, but there was no decrease in the incidence of advanced-stage tumors seen at an older age (Hayashi et al, 1995; Woods et al, 1996). Evaluation of adrenal tumors resected in the neonatal period, whether cystic or solid, showed that

in most, the biologic markers were favorable (Kozakewich et al, 1998). The highly favorable outcome of infants diagnosed with neuroblastoma in the population screening studies led to attempts at expectant observation. These trials demonstrated a high rate of spontaneous resolution (Yamamoto et al, 1998; Yoneda et al, 2001). Spontaneous regression of these perinatally identified lesions also has been demonstrated radiographically (Holgersen et al, 1996). These findings led to a prospective study by the Children's Oncology Group (COG) evaluating treatment of infants with adrenal masses identified in the perinatal or neonatal period in which expectant observation for infants with small lesions with favorable catecholamine ratios was encouraged; this is discussed later.

Pathology

Neuroblastoma, ganglioneuroblastoma, and ganglioneuroma display a spectrum of histologic maturation and differentiation (Fig. 155-1). A grading classification of neuroblastoma, introduced in 1984 by Shimada and subsequently modified by him and others as the International Neuroblastoma Pathology Classification in 1999, has helped to define risk-based subtypes of ganglioneuroblastoma and neuroblastoma (Shimada et al, 1984, 1999a, 1999b). This revised system has been demonstrated to add independent prognostic information beyond the contribution of age that is contained in the system (Sano et al, 2006). Ganglioneuroma is a histologically benign, fully differentiated counterpart of neuroblastoma. It is unclear whether ganglioneuroma arises *de novo* or by maturation of a preexisting neuroblastoma or ganglioneuroblastoma. Metastatic lesions from neuroblastoma have been observed to develop the histology of mature ganglioneuroma, supporting the latter theory (Hayes et al, 1989).

The Shimada classification is an age-linked histopathologic classification. One of its important aspects is determining whether the tumor is stroma poor or stroma rich. Patients with stroma-poor tumors with unfavorable histopathologic features have a very poor prognosis (less than 10% survival) (Shimada et al, 1984). Stroma-rich tumors can be separated into three subgroups: nodular, intermixed, and well differentiated. Tumors in the last two categories more closely resemble ganglioneuroblastoma or immature ganglioneuroma and carry a higher rate of survival. The stroma-poor tumors can be divided into favorable and unfavorable subgroups based on the patient's age at diagnosis, the degree of histologic maturation, and the mitotic rate. When compared with other

Figure 155-2. Magnetic resonance image of child with thoracic ganglioneuroma extending into the spinal canal (arrow).

clinical features, these histologic patterns were independently predictive of outcome (Shimada et al, 1984).

In contrast to neuroblastomas, ganglioneuromas are most often diagnosed in older children and are usually located in the posterior mediastinum and retroperitoneum, with only a small number arising in the adrenal glands (Enzinger and Weiss, 1988). Ganglioneuromas often grow to a very large size before they cause symptoms as a result of compression of adjacent structures or extension into the spinal canal (Benjamin et al, 1972) (Fig. 155-2). Because survival is not influenced by extent of resection, it should be used only in those in whom significant symptoms are present, and aggressive attempts at resection should be avoided (De Bernardi et al, 2008).

Clinical Presentation and Pattern of Spread

The clinical manifestations of neuroblastoma vary widely. Most children have abdominal pain or a palpable mass, but other neuroblastomas are identified because of manifestations of metastatic disease, including bone or joint pain and periorbital ecchymosis. Thoracic lesions may produce respiratory symptoms of cough or dyspnea. Direct extension of the tumor into the spinal canal may produce neurologic deficits as a result of cord compression.

Most primary tumors arise within the abdomen (65%); the frequency of adrenal tumors is slightly higher in children than in infants. Physical examination often reveals a fixed, hard abdominal mass. Pelvic neuroblastoma arising from the organ of Zuckerkandl accounts for 4% of tumors (Haase et al, 1995). Extrinsic compression of the bowel and bladder can produce symptoms of urinary retention and constipation (Fig. 155-3).

Metastases are present in 70% of patients with neuroblastoma at diagnosis and can be responsible for a variety of the clinical signs and symptoms at presentation. A number of unique paraneoplastic syndromes have been associated with both localized and disseminated neuroblastoma. Symptoms produced by catecholamine release may mimic those seen in pheochromocytoma: paroxysmal hypertension, palpitations, flushing, and headache. Secretion of vasoactive intestinal peptide (VIP) by the tumor can produce severe watery diarrhea and hypokalemia (Cooney et al, 1982). Another unusual presentation of neuroblastoma is acute myoclonic encephalopathy, in which patients develop myoclonus, rapid multidirectional eye movements (opsoclonus), and ataxia. It is thought to result from an interaction of antibodies produced against the neuroblastoma to normal neural tissues (Farrelly et al, 1984; Connolly et al, 1997). Although this syndrome is associated with a favorable outcome from an oncologic perspective (Altman and Baehner, 1976), prolonged neurologic impairment, including learning disabilities and developmental delay, is the rule in 70% to 80% of these children, and symptomatic therapy is often required (Russo et al, 1997; Rudnick et al 2001; Mitchell et al 2002). Adre-

Figure 155-3. Magnetic resonance image demonstrating compression of bowel and bladder by a pelvic neuroblastoma.

nocorticotrophic hormone (ACTH) or steroids are the basis of most therapy, but other treatments include high-dose intravenous gamma globulin and cyclophosphamide. A recently completed protocol of the COG evaluated the efficacy of cyclophosphamide plus steroids in patients randomized to receive intravenous gamma globulin or not. Results have not yet been reported.

Diagnosis

Laboratory Evaluation

When sensitive techniques are used, increased levels of urinary metabolites of catecholamines, vanillylmandelic acid (VMA) and homovanillic acid (HVA), are found in 90% to 95% of patients (Williams and Greer, 1963). Therapy with various modalities produces a reduction in catecholamine metabolite excretion in most patients (Gerson and Koop, 1974). These metabolites can be monitored to detect tumor relapse and response to therapy.

Anemia is noted in children with widespread bone marrow involvement. Studies suggest that marrow biopsies add substantially to the detection of marrow involvement by tumor, compared with marrow aspirates alone (Franklin and Pritchard, 1983). It is recommended that two marrow aspirates and two biopsies be performed. In the future, neuroblastoma-specific immunocytology of marrow aspirates may obviate the need for marrow biopsies in most patients (Hsiao et al, 1990).

Imaging

Imaging studies play an important role in the evaluation of a child with neuroblastoma. Plain radiographs may demonstrate a calcified abdominal or posterior mediastinal mass. Computed tomography (CT) and magnetic resonance imaging (MRI) provide more information about the local extent of the primary tumors and vascular involvement. Invasion of the renal parenchyma is not common, but it can be detected radiographically with CT (Albregts et al, 1994). MRI has advantages over CT in evaluating intraspinal tumor extension, which is not uncommon in paravertebral lesions (see Fig. 155-2), and in demonstrating the relationship between the major vessels and the tumor (Azizkhan and Haase, 1993).

Figure 155-4. Magnetic resonance image of pelvic neuroblastoma. The bifurcation of the aorta and iliac vessels are well delineated, showing the relationship to the mass.

(Fig. 155-4). The finding of intratumoral calcifications, vascular encasement, or both on preoperative CT may help distinguish neuroblastoma from Wilms tumor (Dickson et al, 2008). Current COG protocols require both a radionuclide bone scan and metaiodobenzylguanidine (MIBG) scans for staging, but no longer require the classic skeletal survey. MIBG scans use iodine-131 (^{131}I) MIBG (Geatti et al, 1985), which is taken up by the adrenergic secretory vesicles of the tumor cells in both primary and metastatic sites. MIBG scintigraphy can determine the extent of disease and detect tumor recurrence after completion of therapy (Geatti et al, 1985). ^{123}I -MIBG has been shown to be more sensitive than either ^{131}I -MIBG or bone scans in detecting tumor relapse (Kushner et al, 2009). Osseous metastatic lesions occur most commonly in the long bones and skull.

Screening

Mass population screening for neuroblastoma has been widely used in Japan for more than 20 years (Nishi et al, 1987). The goal of screening programs is to detect disease at an earlier stage and to decrease the number of older children with advanced-stage disease, thereby improving survival. In fact, the children diagnosed as a result of screening studies have had almost uniformly favorable survival (>97%) (Suia, 2002). An increased number of infants younger than 1 year of age have been diagnosed through the mass screening program (Ishimoto et al, 1990), and most of these patients have lower-stage tumors (Sawada, 1992). Before mass screening, 20% of patients with neuroblastomas were diagnosed before 1 year of age, compared with 55% after its implementation. However, the number of children older than 1 year of age diagnosed with advanced-stage disease has not decreased. These results suggest that the aggressive advanced-stage tumors in older children did not arise from the low-risk tumors seen in the infants younger than 1 year.

There are biologic differences between tumors diagnosed by screening and those detected clinically (Hayashi et al, 1992). In one review of 48 cases discovered by screening, no tumors were observed to have amplified *MYCN* oncogene expression (Ishimoto et al, 1991), and in a second review of 20 infants, only one who did

poorly had amplification (Hase et al, 2002). Furthermore, 80% had a diploid chromosome pattern, which is also associated with a favorable prognosis. On follow-up, all 48 patients were still alive without tumor. In another series of 357 patients whose tumors were diagnosed by mass screening, the overall survival (OS) rate was 97% (Sawada, 1992). Given the favorable biologic characteristics of tumors discovered by screening, it is possible that many would spontaneously resolve without therapy, particularly given the increased incidence of neuroblastomas seen in the screened population.

Two large prospective population-based studies were conducted in the Province of Quebec and in Germany. These studies demonstrated that urine screening at various ages was successful in identification of neuroblastoma, but there was no decrease in the occurrence of neuroblastoma in older children and its subsequent mortality (Schilling et al, 2002; Woods et al, 2002).

Staging

Staging of neuroblastoma is an important aspect of management. The stage of the disease is a significant prognostic variable that determines adjuvant therapy. The International Neuroblastoma Staging System (INSS) is based on clinical, radiographic, and surgical evaluation of children with neuroblastoma (Brodeur et al, 1993) (Table 155-1). Earlier staging systems provided generally comparable results in terms of distinguishing low-stage, good-prognosis disease from high-stage, poor-prognosis disease. Use of a uniform international system, however, makes comparison of results from various studies much easier to compare. The biggest differences arise when the various systems are applied to those with intermediate-stage disease. It is in this cohort of children where use of the risk group classification, which combines pathologic findings, stage, and several of the biologic markers, best defines the child's risk for progressive disease (Table 155-2) (Katzenstein and Cohn, 1998). Although the classification appears complex, it provides the most accurate assessment of how intense the chemotherapy and radiotherapy must be to cure the child. The challenge with any staging system that uses extent of resection as a component, however, is that a more aggressive approach to a tumor at one institution may result in a different stage for the child than if he or she were treated at another.

A recent effort has been made to preoperatively identify tumors that are resectable without significant surgical risks. The Localised Neuroblastoma European Study Group (LNESEG) defined the radiographic criteria associated with higher surgical morbidity. This group validated that the presence of these criteria was associated with a lower rate of complete resection and a greater risk of surgical complications (Cecchetto et al, 2005). This finding has been confirmed by others (Simon et al, 2008). The International Neuroblastoma Risk Group (INRG) Task Force proposed a staging system based on tumor imaging rather than the extent of surgical resection to address this problem (Monclair et al, 2009). In this system, localized tumors are graded as L1 or L2 based on the absence or presence of one or more of 20 image-defined risk factors (IDRFs), which are primarily related to encasement of vessels or nerves. Metastatic tumors are termed stage M; MS refers to INSS stage 4S in children younger than 18 months, whereas in the INSS the age cutoff is 12 months. These factors were found to be prognostic; of 661 patients, those with L1 disease had a greater 5-year event-free survival (EFS) ($90\% \pm 3\%$) than those with L2 disease ($78\% \pm 4\%$, $P = .001$). A further description of these guidelines has been reported by this group (Brisse et al, 2011). Although a close correlation between presence of IDRFs and resectability of the tumor has been reported, other researchers have not supported this finding (Günther et al, 2011; Rich et al, 2011).

Prognostic Factors

Many variables affect the prognosis of neuroblastoma. In addition to the clinical features, there are now many biologic factors that can be used to stratify patients for treatment.

TABLE 155-1 International Neuroblastoma Staging System

STAGE	DEFINITION
1	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with the primary tumor may be positive).
2A	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically.
2B	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor. Enlarged contralateral lymph nodes must be negative microscopically.
3	Unresectable unilateral tumor infiltrating across the midline,* with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement.
4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs.
4S	Localized primary tumor (as defined for stage 1, 2A, or 2B), with dissemination limited to skin, liver, and/or bone marrow (less than 10% tumor) in infants younger than 1 year.

*The midline is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the opposite side of the vertebral column.

TABLE 155-2 Neuroblastoma Risk Group Classification

RISK GROUP	INSS STAGE	AGE (DAYS)	N-MYC STATUS	DNA INDEX	SHIMADA HISTOPATHOLOGY
Low	1	Any	Any	Any	Any
	2A, 2B	<365	Any	Any	Any
	2A, 2B	≥365	Nonamplified	Any	Any
	2A, 2B	≥365	Amplified	Any	Favorable
	4S	<365	Nonamplified	>1.0	Favorable
Intermediate	3	<365	Nonamplified	Any	Any
	3	≥365	Nonamplified	Any	Favorable
	4	<365	Nonamplified	Any	Any
	4S	<365	Nonamplified	1.0	Favorable
	4S	<365	Nonamplified	Any	Unfavorable
High	2A, 2B	≥365	Amplified	Any	Unfavorable
	3	<365	Amplified	Any	Any
	3	≥365	Nonamplified	Any	Unfavorable
	3	≥365	Amplified	Any	Any
	4	<365	Amplified	Any	Any
	4	≥365	Any	Any	Any
	4S	<365	Amplified	Any	Any

INSS, International Neuroblastoma Staging System.

Clinical Variables

Age remains an important indicator of outcome, as originally reported by Breslow (Breslow and McCann, 1971). Children age 1 year or younger have been recognized historically to have a better survival rate than older children (Nitschke et al, 1988). This may be attributed to more favorable biologic parameters in tumors diagnosed at this age. Recent retrospective reviews have suggested that age is a more “continuous” prognostic variable and that a cutoff of 460 days maximized the outcome difference between the younger and older patients (London et al, 2005), and more recent data from the INRG suggest that an age at diagnosis cutoff of older than 18 months is associated with a higher risk of disease recurrence (Moroz et al, 2011). Teenagers and adults with neuroblastoma have a particularly indolent and relentless disease (Gaspar et al, 2003; Kushner et al, 2003). The site of origin is of significance, with better survival noted for nonadrenal primary tumors (Haase et al, 1995).

Most children with thoracic neuroblastoma are younger at presentation, have localized disease, and have improved survival even when corrected for age and stage (Adams et al, 1993). Tumors at this site are less likely to have MYCN amplification and more likely to have a DNA index greater than 1.0, both favorable prognostic indicators (Morris et al, 1995).

Stage of the disease is a powerful independent prognostic indicator. Virtually all stage 1 patients with complete resection of the primary tumor survive. Stage 2 patients also have a favorable survival prospect, even though there may be incomplete excision (Matthay et al, 1989). Children with advanced regional disease, stage 3 or 4, fare less well and require more intensive treatment. The proportion of patients with localized, regional, or metastatic disease at presentation is age dependent (Nitschke et al, 1988). The OS for stage 1, 2, or 4S disease had a range of 75% to 90%, whereas children with stage 4 disease had a historical 2-year disease-free survival range of 19% to 30% despite intensive therapy, including

bone marrow transplantation. The outcome for infants younger than 1 year is substantially better than for older patients with the same stage of disease.

Stage 4S (S meaning special) is a distinct category referring to infants with small primary tumors and liver, skin, and bone marrow metastases without radiographic evidence of bone metastases. This group of patients has a good prognosis, with OS ranging from 80% to 88%. The INSS criteria later restricted this stage to children with less than 10% bone marrow involvement (Brodeur et al, 1993). This stage accounts for 7% to 10% of all cases of neuroblastoma. Many of these tumors undergo spontaneous regression (Evans et al 1987; Haas et al, 1990). In general, the tumors in infants with stage 4S neuroblastoma have favorable prognostic findings not typically seen in children with stage 4 disease (Hachitanda et al, 1991; Nickerson et al, 2000). Poor outcome in stage 4S patients is associated with elevated serum neuron-specific enolase (>100 nmol/mL), ferritin (>280 ng/mL), and urinary dopamine levels (>2500 nmol/mmol creatinine), as well as MYCN amplification and chromosome 1p deletion (Schleiermacher et al, 2003). Most deaths in this group are in infants younger than 2 months with extensive abdominal involvement and with respiratory compromise or disseminated intravascular coagulation (Nickerson et al, 2000).

Biologic Variables

The presence of homogeneously staining regions and double-minute chromosomes was noted in approximately one third of neuroblastoma tumors. These abnormalities are cytogenetic manifestations of gene amplification, and it was subsequently found that the MYCN oncogene was mapped to these regions. The association of MYCN amplification with the pathogenesis of neuroblastoma is unclear, but MYCN amplification is almost always present at the time of diagnosis (Brodeur, 1991). Seeger and colleagues (1985, 1988) showed that MYCN amplification is associated with rapid tumor progression and a poor prognosis. Amplification is found in 5% to 10% of patients with low-stage or stage 4S (Hachitanda et al, 1991) but in 30% to 40% of those with advanced-stage disease (Brodeur and Fong, 1989; Brodeur, 1990). The poor prognosis associated with MYCN amplification is independent of patient age or stage of disease at presentation (Iehara et al, 2006). However, not all patients with a poor outcome have MYCN amplification. Many advanced-stage tumors lack MYCN at diagnosis, and recurrence or progression of disease develops in most of these patients. A full INRG analytic cohort of 8800 patients from North America, Europe, and Japan provided an extensive analysis of the survival implications of multiple genetic characteristics shown in Table 155-2 (Cohn et al, 2009). Again, MYCN status was the most powerful predictor of EFS and OS along with ploidy, 11q, and 1p status and, to a lesser extent, 17q gain.

DNA content of tumor cells and ploidy number has been reported to have prognostic value in patients with neuroblastoma (Cohn et al, 1990). Studies of DNA content measured by flow cytometry showed that a "hyperdiploid" karyotype (or increased DNA content) was associated with a favorable outcome (Look et al, 1984; Kusafuka et al, 1994). DNA diploidy and tetraploidy were associated with decreased survival. A review of 2660 children with localized neuroblastoma registered with the INRG database evaluated tumor ploidy in children with MYCN-amplified tumors (Bagatell et al, 2009). They reported an improved prognosis in children with hyperdiploid tumors compared with diploid tumors. This could be used to identify children for reduction in therapy.

Deletions of the short arm of chromosome 1 have been found in 70% to 80% of the near-diploid tumors that have been karyotyped (Brodeur and Fong, 1989; Brodeur, 1990). Preliminary studies suggested a correlation between 1p deletion and poor survival (Brodeur and Fong, 1989; Hayashi et al, 1989). Children currently treated on protocols of the COG are assigned to a risk group that is determined by age, stage of disease, MYCN status, histologic grade, and DNA ploidy (Katzenstein et al, 1998) (see Table 155-2). Other factors that have been demonstrated to have prognostic significance, although they are often associated with these genetic

abnormalities, include expression of the gene encoding the high-affinity nerve growth factor receptor (termed *TRKA* proto-oncogene) and the low-affinity nerve growth factor receptor (Tanaka et al, 1995). Both are favorable prognostic predictors and are inversely related to amplification of the MYCN oncogene (Nakagawara et al, 1993). Lack of expression of CD44 glycoprotein on the tumor cell surface and increased levels of serum ferritin, serum neuron-specific enolase, and serum lactate dehydrogenase are all adverse prognostic factors (Chan et al, 1991; Silber et al, 1991). They have not, however, been shown by multivariate analysis to be independently predictive from age, stage, ploidy, and MYCN status. Telomere length has also been described as a significant prognostic parameter, and in a cohort of high-risk patients, it was the sole significant parameter that identified a group of patients with a favorable prognosis (Ohali et al, 2006).

Treatment

The treatment modalities primarily used in the management of neuroblastoma are surgery, chemotherapy, and radiation therapy. The role of each in individual patients varies depending on tumor stage, age, and biologic prognostic factors. These can be used to stratify patients into favorable and unfavorable categories by risk group (see Table 155-2).

Surgery

The goals of surgery are to establish the diagnosis, stage the tumor, excise the tumor (if localized), and provide tissue for biologic studies. Resectability of the primary tumor should take into consideration tumor location, mobility, relationship to major vessels (IDRFs), and overall prognosis of the patient. Neoadjuvant chemotherapy, given the efficacy of modern agents, is very successful in reducing the size of primary tumors. Sacrifice of vital structures to achieve resection at diagnosis should be avoided, particularly in young children in whom prognosis is excellent.

Low-Risk Disease (Stages 1, 2, and 4S). Children with stage 1 neuroblastoma have a disease-free survival rate of greater than 90% with surgical excision alone (O'Neill et al, 1985; Nitschke et al, 1988; De Bernardi et al, 1995). Chemotherapy is indicated only in the event of recurrence unless the child has MYCN amplification and unfavorable histology. The Pediatric Oncology Group reviewed 101 children with localized neuroblastoma who had complete gross excision of the primary tumor (Nitschke et al, 1988). Nine patients experienced relapse, but 6 were salvaged with chemotherapy. Radiation therapy has no role in this subset of patients. With current use of the risk factor grading, children with recurrence in the past may be identified now as the small number with adverse biologic markers. In a comparable study from the Children's Cancer Group, 374 stage 1 and 2 patients were treated primarily by resection (Perez et al, 2000). EFS and OS for stage 1 patients were $93\% \pm 3\%$ and $99\% \pm 1\%$, respectively, compared with $81\% \pm 4\%$ and $98\% \pm 2\%$ for stage 2 patients, respectively. Supplemental treatment was required in only 10% of stage 1 and 20% of stage 2 patients, and excellent OS was achieved in the stage 2 patients. MYCN amplification, unfavorable histology, age greater than 2 years, and positive lymph nodes predicted a lower OS. A recent COG trial of asymptomatic INSS stages 2A and 2B patients were treated with surgery alone (Strother et al, 2012). Chemotherapy in this study was reserved for patients with symptomatic disease or considered at risk for its development, or those with less than 50% resection with unresectable progressive disease after surgery. For all 915 enrolled patients, the 5-year EFS and OS were $89\% \pm 1\%$ and $97\% \pm 1\%$. In the cohort with stage 2B disease, the EFS and OS were significantly lower for those with unfavorable-histology or diploid tumors and OS was significantly lower for those 18 months or younger. The 5-year OS rates for patients with stage 1 and 4S were $99\% \pm 1\%$ and $91\% \pm 1\%$, respectively. Of patients observed after surgery, 11.1% experienced recurrence or progressive disease.

Radical resection resulting in removal of normal organs, particularly the kidney, is not justified in this group of patients. Radiation

Figure 155-5. Magnetic resonance image before and after chemotherapy showing marked reduction in size of right suprarenal neuroblastoma. A, Before chemotherapy. B, After chemotherapy.

of the local tumor bed has been advocated for treatment of residual disease in stage 2 cases. However, a review of 156 patients with stage 2 neuroblastoma found a 90%, 6-year, progression-free survival rate regardless of whether radiation therapy was used (Matthay et al, 1989). Therefore, radiation should be reserved for those relapsed patients who fail to respond to either primary or secondary chemotherapy. In stage 3 disease, or in stage 2 with extensive tumor around the kidney and renal vessels, preoperative treatment with chemotherapy significantly decreases the risk of nephrectomy as a result of resection of the tumor (Shamberger et al, 1998) (Fig. 155-5).

The generally favorable behavior of stage 4S disease has been explained by our current knowledge of the significance of biologic markers. The vast majority of these infants have tumors with entirely favorable markers, explaining their favorable behavior. However, a small fraction have adverse markers, and it is these children who have progressive disease that often is fatal. Resection of the primary is not mandatory (Nickerson et al, 1985; Evans et al, 1987). Although excellent survival has been reported after surgery (Martinez et al, 1992), information regarding histologic prognostic factors was not available for all of these patients. In a review of 110 infants with stage 4S disease, the entire cohort had an estimated 3-year survival rate of $85\% \pm 4\%$ (Katzenstein et al, 1998). This rate was significantly decreased to $6\% \pm 12\%$ for infants whose tumors were diploid; to $44\% \pm 33\%$ for those with *MYCN* amplification; and to $33\% \pm 19\%$ for those with unfavorable histology. Of note, there was no statistical difference in survival rate for infants who underwent complete resection of their primary tumor compared with those who had partial resection or only biopsy (Katzenstein et al, 1998; Nickerson et al, 2000; von Schweinitz et al, 2002). Patients with extensive metastatic disease and *MYCN* amplification represent a high-risk group (Martinez et al, 1992). These patients should be considered for a more aggressive treatment with multimodal therapy, according to the risk group classification (see Table 155-2) (Schleiermacher et al, 2003). Those with favorable biologic markers and no symptoms can be followed with supportive care and limited chemotherapy. Intensive chemotherapy is reserved for those with adverse markers, although these infants do poorly even with therapy.

Perinatal Neuroblastoma. Based on the favorable outcomes of infants identified with neuroblastoma from the screening studies discussed earlier and the favorable biology of these tumors, a prospective study was performed by the COG to assess the outcome of

expectant observation for neuroblastoma in young infants. Infants were enrolled who were younger than 6 months with small adrenal masses (≤ 16 mL in volume if solid or ≤ 65 mL if the mass was at least 25% cystic) and no evidence of spread beyond the primary tumor (Nuchtern et al, 2012). Serial abdominal sonograms and urinary catecholamine levels were obtained during a 90-week interval. Patients with a 50% increase in the volume of the mass or urine catecholamine values or an increase in the HVA-to-VMA ratio greater than 2 were referred for surgical resection. Eighty-seven infants were enrolled; in 83, observation was elected, and in 4, immediate surgery. Sixteen infants in the observation arm ultimately had surgery; 8 had INSS stage 1 neuroblastoma, 2 had higher-stage neuroblastoma (2B and 4S), 2 had a low-grade adrenocortical neoplasm, 2 had adrenal hemorrhage, and 2 had extralobar pulmonary sequestration. The 2 adrenal cortical tumors were resected because of a greater than 50% increase in tumor volume. The 3-year EFS for a neuroblastoma event was $97.7\% \pm 2.2\%$ within the entire cohort of infants. The 3-year OS was 100% with a median follow-up of 3.2 years. Following this protocol, 81% of the infants avoided resection, supporting the role of expectant observation in this selected population. A future study is planned to expand the size and location of these tumors.

Intermediate- and High-Risk Disease (Stages 3 and 4). There is debate regarding the extent of surgical resection that is required for stage 3 lesions. A report from the Children's Cancer Group of 58 patients with stage 3 disease found that 8 of 12 patients with initial complete excision, and 12 of 14 with subsequent resection of the primary tumor, were long-term survivors (Haase et al, 1989). This result contrasts with only 9 of 32 survivors among patients in whom complete tumor excision could not be accomplished. Significant morbidity was reported in association with the surgical procedures, including 21 major complications. The Italian Cooperative Group for Neuroblastoma found that complete resection after chemotherapy of extensive unresectable neuroblastoma was associated with improved survival, compared with partial resection only (Garaventa et al, 1993). Similar results have been noted by others (Le Tourneau et al, 1985; O'Neill et al, 1985; Powis et al, 1996). It has been suggested by some that even children with stage 3 disease do not need cytotoxic therapy if the biologic marker *MYCN* amplification is not present (Kushner et al, 1996). These results are not widely accepted, however, and confirmatory studies are required before this policy can be widely adopted.

In general, children with bulky pelvic tumors do quite well even with limited residual disease (Leclair et al, 2004). Extensive surgery at this site has been associated with long-term neurologic sequelae; thus the extent of resection must be balanced against this morbidity (Crucetti et al, 2000).

A recent study from the COG of intermediate-risk patients attempted to decrease the intensity of therapy while maintaining outcomes (Baker et al, 2010). Criteria included intermediate-risk neuroblastoma without *MYCN* including infants younger than 365 days with stage 3 or 4 disease, children older than 365 days who had stage 3 tumors with favorable histopathologic features, and infants who had stage 4S disease with a diploid DNA index or unfavorable histopathologic features. Children received four active agents in this disease: cyclophosphamide, doxorubicin (DOX), carboplatin, and etoposide. They received four cycles if they had favorable biology or eight cycles if they had unfavorable biology. Radiotherapy was used only for progressive disease or in patients with an unresectable primary tumor with unfavorable prognostic features. The 3-year estimate of OS for the entire group was $96\% \pm 1\%$; $98\% \pm 1\%$ for those with favorable biologic features and $93\% \pm 2\%$ for those with unfavorable biologic features. These findings supported the reduction in therapy for this cohort of patients. Complete data regarding surgical intervention were available for 235 patients. Gross total resection was achieved in 89 patients, near-total resection ($>90\%$ of the tumor) in 51, major resection ($>50\%$ of the tumor) in 26, and limited resection ($\leq 50\%$ of the tumor) in 54. No significant difference was demonstrated in OS according to the extent of resection (complete vs. incomplete $P = .37$). Of note, 28% of patients had one or more complications.

There is conflicting evidence regarding the benefit of extensive resection in children with stage 4 disease between studies that support (Le Tourneau et al, 1985; Haase et al, 1991; Tsuchida et al, 1992; La Quaglia et al, 1994; Chamberlain et al, 1995; DeCou et al, 1995; Yokoyama et al, 1995; Kuroda et al, 2003; Adkins et al, 2004; La Quaglia et al, 2004; Koh et al, 2005; McGregor et al, 2005) and those that refute that approach (Sitarz et al, 1983; Matsumura et al, 1988; Adams et al, 1993; Losty et al, 1993; Kiely, 1994; Kaneko et al, 1997; Castel et al, 2002; von Schweinitz et al, 2002; Simon et al, 2013). In a retrospective review, Kiely (1994) compared the results of radical tumor resection with those of more conventional surgery in patients with stage 3 or 4 disease. Kiely found no difference in survival between 46 patients treated with radical surgical procedures and 34 patients treated with more conventional surgery. Shorter and colleagues (1995) also did not find any evidence that the extent of surgical resection had an impact on the survival of stage 4 patients. In these nonrandomized studies, it has been difficult to determine whether improved survival in those with complete resection has been a result of the more favorable intrinsic biology of the tumor allowing resection or truly a result of the completeness of resection. La Quaglia assessed the results in 33 nonredundant studies that provided adequate surgical data for analysis of survival (La Quaglia, 2014). The analysis included 2599 patients for the survival analysis and 412 in the analysis of local progression. Meta-analysis revealed that the relative risk of mortality for stage 3 and 4 patients who had more than 90% resection was 0.67 (95% confidence interval [CI] 0.59 to 0.77) compared with those with a lesser resection. For stage 4 patients alone the relative risk was 0.75 (95% CI 0.62 to 0.92). The relative risk of local recurrence or progression in patients with stage 4 disease was 0.38 (95% CI 0.27 to 0.53) for those who underwent extensive primary resection compared with those who did not.

As the intensity of the therapy increases, including the use of autologous bone marrow transplantation and control of distant metastasis, the impact of maximal local control may become apparent. The combination of gross total resection and external beam irradiation has achieved local control in 84% to 90% of children (Wolden et al, 2000; Kushner et al, 2001). In another series of reports, intensive chemotherapy followed by double autologous bone marrow transplantation, aggressive surgical resection, and radiotherapy achieved an OS of 56% and a local recurrence rate of only 2.6% (Marcus et al, 2003; von Allmen et al, 2005).

Usually the safest approach for advanced tumors is to defer resection until after initial chemotherapy (Berthold et al, 1989; Shamberger et al, 1991; Shochat, 1992; La Quaglia et al, 1994; Black et al, 1996). The tumors are smaller and firmer, with less risk of rupture and hemorrhage after chemotherapy, resulting in a decreased rate of complications, particularly nephrectomy (Shamberger et al, 1998) (see Fig. 155-5). One specific complication that is encountered after resection of extensive tumor surrounding the celiac axis and the superior mesenteric artery is diarrhea (Kiely, 1994). It is thought to result from resection of the autonomic nerves to the gut found anterior to the aorta at the base of the superior mesenteric artery and the celiac axis (Rees et al, 1998). Preoperative chemotherapy does appear to increase the proportion of children able to achieve a complete resection (Adkins et al, 2004).

Surgery usually is performed 13 to 18 weeks after initiation of chemotherapy, allowing three to four courses of treatment (Azizkhan and Haase, 1993). Some tumors remain inoperable even after chemotherapy.

Infants younger than 1 year with extensive local disease or stage 4 disease comprise a special subset of patients. They have historically fared much better than children older than 1 year of age with comparable disease, but not as well as infants with stage 4S disease. It is now recognized that the biologic markers can be used to identify which infants have high-risk disease and require intensive therapy and which have intermediate-risk disease requiring less intensive therapy. The SIOPEX Infant Neuroblastoma European Study reported 120 infants with localized tumors and no *MYCN* amplification who were deemed unresectable based on IDRFs (Rubie et al, 2011). These infants were treated with low-dose cyclophosphamide and vincristine (VCR) repeated once to three times every 2 weeks until surgical excision could be safely performed. Infants with either one life-threatening symptom or an insufficient response were given carboplatin and etoposide (CaE), sometimes followed by VCR, cyclophosphamide, and DOX. Seventy-nine received the two-drug therapy with VCR, and 49 received CaE because of insufficient response. Thirty-two infants had life-threatening symptoms, and of these 30 received CaE. Anthracyclines were used in 46 infants. Surgery was performed in 102 infants, leading to gross surgical excision in 93. Relapse occurred in 12 patients (9 local and 3 distant). The 5-year OS and EFS were $9\% \pm 1\%$ and $90\% \pm 3\%$, respectively. The low-dose chemotherapy without an anthracycline was effective in 62% of these infants with an unresectable tumor and no *MYCN* amplification.

In a large cohort (134 infants), *MYCN* amplification, serum ferritin, Shimada histopathologic classification, and bone marrow involvement by immunocytology were analyzed. Although each factor had prognostic significance by univariate analysis, only *MYCN* amplification was significant by multivariate analysis; the EFS for infants without *MYCN* amplification was $93\% \pm 4\%$ versus $10\% \pm 7\%$ in those with amplification despite intensive therapy (Schmidt et al, 2000).

Recent trials in Europe evaluated these infants without *MYCN* amplification and achieved excellent survival (OS of 97.6% at 2 years) without chemotherapy in those with primaries extending across the midline or a positive skeletal survey (De Bernardi et al, 2009). Infants with overt metastases to the skeleton, lung, and central nervous system (CNS) were treated with a minimum of four chemotherapy courses and achieved a 2-year OS of 95.6%.

Chemotherapy

A variety of multiagent treatment regimens have been developed to treat high-risk patients with neuroblastoma. The goal of this treatment intensification is better disease control. Although initial response rates are improving, with a prolonged time to progression of disease, relapse continues to be a major problem.

The dose intensification of chemotherapy needed for local tumor control results in significant myelosuppression, limiting the amount of therapy that can be given. This has prompted the use of autologous bone marrow transplantation after sublethal chemotherapy or total-body irradiation. The use of marrow-ablative

chemoradiotherapy followed by autologous marrow reinfusion has resulted in complete remission in up to 50% of patients with recurrent stage 4 disease (Moss et al, 1987; Seeger et al, 1991; Dinndorf et al, 1992; Mugishima et al, 1994; Matthay et al, 1995; Grupp et al, 2000). However, a significant problem is the risk for late relapse. The randomized clinical trial of the German Society of Paediatric Oncology and Hematology of high-risk neuroblastoma showed improved EFS at 3 years with myeloablative therapy and autologous stem cell rescue compared with maintenance chemotherapy (Berthold et al, 2005). These results were similar to those of the COG study (Matthay et al, 1999). Regrettably, the OS rates were not statistically different in either study at initial report. A recent update of the latter study reveals that the 5-year OS of the patients receiving the autologous bone marrow transplant was improved (Matthay et al, 2009).

A subsequent study by the COG addressed the issue of the need for “purging” of the bone marrow before return to the patient to remove any potential remaining neuroblastoma cells. This study was terminated when interim analysis showed no difference in outcome between the two groups. A further study addressed the benefit between a single versus a paired autologous transplant to see if additional intensification would improve outcome. This study has completed enrollment, but results are not yet available.

The presence of bulky disease results in increased failure. Tumor debulking with surgery or radiation therapy is warranted before autologous bone marrow transplantation. There are many questions yet to be resolved about this modality of treatment. Toxicity of bone marrow transplantation can be lethal, and the long-term complications in patients with successful transplantation are unknown. However, these risks are acceptable given that long-term survival is difficult to achieve without such aggressive therapy.

New agents in phase I and II trials for relapsed neuroblastoma include temozolomide, irinotecan, and topotecan (Kushner et al, 2006; Rubie et al, 2006; Simon et al, 2007). As efficacy is established, they will be advanced into clinical trials for high-risk tumors with a goal of improving the overall outcome.

New Innovative Biologic Therapies

Because increasing the intensity of chemotherapy appears to have reached its limit with the use of double autologous bone marrow transplantation, other routes of treatment must be identified. The use of biologic modifiers is being investigated (Villablanca et al, 1995). 13-*cis*-Retinoic acid produces differentiation of neuroblastoma in cell cultures. It was given for a 6-month period after cytotoxic therapy in children with advanced-stage disease and significantly decreased the frequency of relapse (Matthay et al, 1999). Long-term follow up has shown that the 5-year OS is improved with the use of 13-*cis*-retinoic acid in these children after transplant or intensive chemotherapy (Matthay et al, 2009). Other avenues of treatment in current phase I and phase II trials include vaccine and antiangiogenic therapy. Antibody therapy against the GD2 cell surface marker occurring in neuroblastoma has been shown to be an effective adjuvant therapy in combination with granulocyte-macrophage colony-stimulating factor and interleukin-2 along with 13-*cis*-retinoic acid after autologous bone marrow transplant compared with 13-*cis*-retinoic acid alone (Yu et al, 2010).

A new synthetic retinoid, fenretinide, which has produced apoptosis rather than differentiation in neuroblastoma cell lines, is also in clinical trials for maintenance therapy. It has been shown to be effective against some neuroblastoma cell lines that are resistant to 13-*cis*-retinoic acid.

Inhibition of angiogenesis is another appealing avenue of therapy in this very vascular tumor, particularly once there is minimal residual disease. Another modality in the treatment of metastatic neuroblastoma is the use of ¹³¹I-MIBG (Hutchinson et al, 1992). The finding that both the primary tumor and metastatic areas take up this radiotracer suggested the possibility that therapeutic doses can be delivered to the tumor. Preliminary analysis indicates that objective responses do occur in terms of reduction of tumor volume, even in previously heavily treated patients (Howard

et al, 2005; Matthay et al, 2007). Significant myelosuppression is seen with dose escalation, however, and stem cell support is required.

Radiotherapy

Radiotherapy is effective for local control in neuroblastoma, and risk of local relapse can be correlated with the biologic markers. Although irradiation has not provided a benefit in low-stage tumors, it has increased local control in children with advanced stage 4 or bulky stage 3 tumors (Matthay et al, 1989; Castleberry et al, 1991; Evans et al, 1996). A randomized controlled trial to evaluate the efficacy of local control between radiotherapy alone and surgery has not been performed. Doses of external beam irradiation used have ranged from 15 to 30 Gy, depending on the patient's age, location of the tumor, and extent of residual disease.

Intraoperative radiation therapy has been used for patients with unresectable disease. This technique has the advantage of delivering a higher dose of radiation to the operative field while sparing normal adjacent tissues (Leavey et al, 1997). Although its use has been promoted, it has not been convincingly demonstrated to improve control when compared with external beam irradiation (Haas-Kogan et al, 2000).

Spinal Cord Compression

Extension of tumor into the spinal canal produces symptoms of spinal cord compression in up to 5% of patients with neuroblastoma (De Bernardi et al, 2001); up to 13% of patients have radiographic evidence of extension into the spinal canal (Plantaz et al, 1996). These children have been treated by decompressive laminectomy, radiotherapy, or chemotherapy. Neurologic outcome has been similar by all modalities and, regrettably, patients with severe motor deficits typically recover little function (De Bernardi et al, 2001; Katzenstein et al, 2001). Because of the delayed complications of scoliosis after laminectomy, current recommendations are to initiate treatment with chemotherapy and reserve laminectomy for children with progressive neurologic deterioration (Katzenstein et al, 2001). Radiotherapy is now avoided in general, because of its adverse effect on growth of the spine.

KEY POINTS: NEUROBLASTOMA

- Neuroblastoma is the most common extracranial solid neoplasm in children.
- Amplification of the *MYCN* oncogene is found in 20% to 25% of primary tumors and is an adverse prognostic factor. It is present in 40% of patients with advanced-stage disease but in only 5% to 10% of children with low-stage disease. It is associated with rapid tumor progression and poor outcome from treatment and is independent of age or stage of disease.
- Children 1 year old or younger have a better survival rate than older children. This may be attributed to more favorable biologic parameters in tumors diagnosed at this age.
- Children with stage 1 neuroblastoma have a disease-free survival rate of greater than 90% with surgical excision alone.
- Infants younger than 6 months with localized small adrenal masses can be managed with serial observation. Surgical resection can be avoided in 80% of such patients.

WILMS TUMOR

Wilms tumor, or nephroblastoma, is the most common primary malignant renal tumor of childhood. It is an embryonal tumor that develops from remnants of immature kidney. Treatment of patients with nephroblastoma has been extensively investigated in a number of large randomized clinical trials in North America and Europe.

TABLE 155-3 Gene Mutations in Wilms Tumors

GENE	TYPE OF MUTATION	FREQUENCY (%)	SOMATIC OR GERMLINE
11p15	H19 epimutation Paternal uniparental disomy	74	Both
<i>WTX</i>	Deletion or insertion Nonsense	33	Somatic only
<i>WT1</i>	Deletion or insertion Missense and nonsense	21	Both
<i>CTNNB1</i>	In-frame deletions Missense	20	Somatic only
<i>TP53</i>	Missense	4	Both

The focus of current trials is on reducing the morbidity of treatment for low-risk patients and reserving more intensive treatment for high-risk patients for whom survival remains poor. This section outlines current recommendations for treatment and reviews the latest developments in the biology of Wilms tumor.

Epidemiology

Wilms tumor accounts for 6% to 7% of all childhood cancers. It is the most common renal tumor of childhood, accounting for 95% of all kidney cancers in children under the age of 15 in the United States (Ali et al, 2012; Howlader et al, 2013). According to the Surveillance, Epidemiology, and End Results (SEER) registry, the average annual age-adjusted incidence rate of Wilms tumor is 8.0 per million (Breslow et al, 1993; Bernstein et al, 1999). More than 80% of patients are diagnosed before 5 years of age, with a median age of 3.5 years. Nevertheless, older children and occasionally even adults can be affected (Arrigo et al, 1990; Kalapurakal et al, 2004; Ali et al, 2012). The median age at diagnosis is lower in children with bilateral Wilms tumor (Breslow et al, 1993). Wilms tumor manifests at an earlier age among males with both unilateral and bilateral tumors.

In North America, Wilms tumor occurs slightly more frequently in females than in males. With regard to ethnicity, the incidence of Wilms tumor is lower in East Asian populations and higher in black populations compared with the incidence reported for North American and European Caucasians (Breslow et al, 1994; Fukuzawa et al, 2004; Axt et al, 2011). The fact that such variations are more closely associated with race than geography suggests that environmental risk factors likely play a minor etiologic role, certainly in comparison with adult epithelial cancers (Breslow et al, 1993). Black children often have a more advanced stage of disease at presentation, but it is not clear if this is related to tumor biology or reflects delays in diagnosis resulting from impaired access to health care (Axt et al, 2011). Several epidemiologic studies have investigated occupational, environmental, and lifestyle factors as risk factors for Wilms tumor. Although some studies have suggested that a number of parental exposures might be associated with an increased risk of Wilms tumor, very few have been established conclusively (Breslow et al, 1993).

Biology and Genetics

Children with Wilms tumor have been extensively studied to determine the role of genetic alterations in tumor development. We now recognize that the majority of Wilms tumors arise from somatic mutations restricted to tumor tissue and a much smaller percentage originate from germline mutations (Ruteshouser et al, 2008; Scott et al, 2012). It is apparent that several genetic events result in Wilms tumorigenesis and that the Knudson two-hit model of cancer formation does not explain most cases (Knudson and Strong, 1972b). Approximately 10% of children with Wilms tumor have congenital anomalies and syndromes; 5% to 10% of tumors are bilateral and

multicentric, and 1% to 2% are familial. These subsets of patients are the ones in whom the most thorough evaluation for genetic abnormalities have been conducted. A number of genes have been identified as playing a role in the development of Wilms tumor (Table 155-3).

WT1

The first gene mutation described in Wilms tumor was *WT1*, with both somatic and germline mutations noted. The identification and subsequent cloning of *WT1* resulted from cytogenetic observations of gross deletions at chromosome 11p13 in patients with the WAGR syndrome (Wilms tumor, aniridia, genital anomalies, mental retardation). These children were shown to have heterozygous germline deletions at 11p13 (Riccardi et al, 1978). Subsequent molecular analysis of the DNA mapping of this specific region led to the identification of *WT1* in 1990 (Bonetta et al, 1990; Call et al, 1990). *WT1* mutations are often associated with β -catenin (*CTNNB1*) mutations, defining a specific genetic subset of Wilms tumor (Li et al, 2004; Royer-Pokora et al, 2008). This subset has been called the ideal type 1 Wilms tumor (Breslow et al, 2006b). It is characterized by a stromal-predominant favorable histology, intralobar nephrogenic rests (ILNRs), early onset of Wilms tumor, and genitourinary abnormalities in males. Wilms tumors from patients with WAGR and Denys-Drash syndrome (DDS) belong to this subtype of tumors.

Aniridia, found in 1.1% of Wilms tumor patients, is caused by an abnormality of the *PAX6* gene located adjacent to the *WT1* gene. Aniridia patients with visible (microscopic) chromosomal deletions that include *WT1* were noted to be prone to the development of Wilms tumor (Muto et al, 2002). Fluorescence in situ hybridization analysis of aniridia patients has been used to identify submicroscopic deletions of *WT1* and is also a useful predictor of Wilms tumor development (van Heyningen et al, 2007). Wilms tumor will develop in approximately 40% to 70% of aniridia patients with deletions of *WT1*. Conversely, aniridia patients with normal *WT1* do not develop Wilms tumor (Grenskov et al, 2001; van Heyningen et al, 2007).

The *WT1* gene is important for normal kidney and gonadal development. *WT1* encodes a zinc finger transcription regulating mesenchymal to epithelial transition in kidney development (Pritchard-Jones 1990; Dressler, 1995). *WT1* is necessary for ureteric bud outgrowth and is also important in nephrogenesis. Targeted mutation of the *WT1* gene in mice results in failure of kidney and gonadal development (Kreidberg et al, 1997). DDS is the specific association of male pseudohermaphroditism, renal mesangial sclerosis, and nephroblastoma (Drash et al, 1970). The syndrome is caused by point mutations in the zinc finger DNA binding region of *WT1* (Coppes et al, 1993). More than 90% of DDS patients harbor germline point mutations in only one *WT1* allele (Pelletier et al, 1991; Coppes et al, 1992). Therefore the *WT1* mutation acts dominantly with respect to genitourinary abnormalities. The fact that the phenotype resulting from these heterozygous mutations is

far more severe than that resulting from constitutional deletion of one *WT1* allele (i.e., WAGR patients) suggests that the Denys-Drash mutations do not result in inactivation of the *WT1* protein, but rather in the production of a dysfunctional *WT1* protein. It is postulated that this abnormally expressed protein alters regulation of transcription and urogenital development. The majority of these patients progress to end-stage renal disease. Nephropathy usually manifests early in life, and renal biopsy demonstrates mesangial sclerosis. Some *WT1* mutations can lead to an incomplete DDS phenotype, with varying degrees of genitourinary anomalies, renal pathologies, and penetrance of Wilms tumor (McTaggart et al, 2001). Although XY individuals have been reported most often, DDS has been reported in genotypic or phenotypic females. WAGR and DDS patients are more likely to have bilateral tumors and are diagnosed at a younger age (Breslow et al, 2003, 2006b).

This risk for renal insufficiency in DDS is shared by children with WAGR and children with genitourinary abnormalities, all associated with a *WT1* mutation (Diller et al, 1998). **WAGR patients and those with genitourinary abnormalities have an increased risk of renal failure if they survive into puberty** (Breslow et al, 2000, 2005). Genitourinary anomalies (renal fusion anomalies, cryptorchidism, hypospadias) are present in 4.5% of patients with Wilms tumor (Breslow et al, 1993). The incidence of *WT1* mutations in patients with Wilms tumor not associated with any genitourinary abnormality is approximately 2% (Little et al, 2004). Recent studies of nontumoral renal tissue in children with WAGR and DDS have demonstrated smaller glomerular diameters than in controls (Dahan et al, 2007). This suggests a specific defect of *WT1* function during renal development that leads to subsequent deterioration in renal function with age.

WT1 was originally considered to be a classic tumor suppressor gene, and the loss of both copies or mutations of this gene would lead to Wilms tumor development (Rauscher, 1993). Although this may be the case for some tumors, only 20% of patients with Wilms tumor have a mutation in the germline or in tumor tissue (Diller et al 1998; Ruteshouser et al, 2008). It is well established that most constitutional cancer syndrome mutations, including *WT1*, are associated with younger age of onset. However, recent studies have also shown that the median age of onset in children with somatic *WT1* mutations was 14 months. It is postulated that *WT1* mutations are associated with a more rapid progression to Wilms tumor than other molecular abnormalities (Scott et al, 2012).

WTX

Another tumor suppressor gene, *WTX* is targeted by somatic mutations in up to 30% of cases of Wilms tumor, the most common type of pediatric kidney cancer (Rivera et al, 2007). Most tumors have deletions of the entire *WTX* gene, but one third of *WTX*-mutated Wilms tumors carry truncating mutations or missense mutations. The functional importance of the missense alterations is unclear, because the missense alteration can be present in normal tissue from the same patient, whereas the deletion and truncation mutations are always specific to the tumor. The location of *WTX* on the X chromosome is of particular interest because it is inactivated by a monoallelic or "single-hit" event rather than by the classical biallelic inactivation of autosomal tumor suppressor genes. It targets the single X chromosome in males and the active X chromosome in females with tumors and occurs at comparable frequencies in males and females. Initially it was reported that tumors caused by *WTX* mutations lack *WT1* mutations. Subsequently, it has been observed that *WTX* mutations occur with equivalent frequency in tumors with or without mutations in *WT1* and *CTNNB1* (Ruteshouser et al, 2008). *WTX*, like *WT1*, appears to play a role in the Wnt/ β -catenin signaling pathway. Mutations in *WT1*, *WTX*, and *CTNNB1* provide the genetic basis for about one third of Wilms tumors.

11p15

Additional molecular alterations are observed at the chromosome 11p15 locus, which contains a cluster of imprinted genes (Koufos

et al, 1989; Mannens et al, 1990). LOH or loss of imprinting (LOI) on 11p15 occurs in up to 70% of tumors (Scott et al, 2012). A *WT2* locus has been postulated for 11p15, but so far the respective gene has not been identified. **This region is known to harbor genes for the Beckwith-Wiedemann syndrome (BWS) and other syndromes with overgrowth features** (Koufos et al, 1989). These include **hemihypertrophy, which may occur alone or as part of BWS or Perlman, Soto, and Simpson-Golabi-Behmel syndromes** (Perlman et al, 1975; Neri et al, 1998). Most cases of BWS are sporadic, but up to 15% exhibit heritable characteristics with apparent autosomal dominant inheritance. The BWS critical region on 11p15 includes two domains of imprinted genes located in close proximity in band 11p15. Imprinting center region 1 (ICR1) regulates the expression of *IGF2* and *H19*, and center 2 (ICR2) regulates *CDKN1C*, *KCNQ10T1*, and *KCNQ1*. These imprinting centers are differentially methylated on the paternal and maternal allele, leading to expression of only one parent-specific allele (Choufani et al, 2013).

Wilms tumor associated with epigenetic alterations in the 11p15 region has been termed the ideal type 2 Wilms tumor (Breslow et al, 2006b). A type 2 Wilms tumor is characterized by limited nephrogenic differentiation and a mostly blastemal or epithelial-type histology; patients develop tumors at a later age and have a heavier birth weight. **The risk of nephroblastoma in children with BWS and hemihypertrophy is estimated to be 4% to 10%; 21% of children have bilateral disease at presentation** (Beckwith, 1996; DeBaun and Tucker, 1998; Porteus et al, 2000). The mean age at diagnosis of Wilms tumor in BWS and hemihypertrophy patients is similar to that of the general Wilms tumor population (Breslow et al, 1993). Adrenocortical neoplasms and hepatoblastoma also occur with increased frequency in BWS. Children with BWS found to have nephromegaly (kidneys greater than or equal to the 95th percentile of age-adjusted renal length) are at the greatest risk for the development of Wilms tumor (DeBaun et al, 1998). Investigators have been able to correlate genetic changes to identify which BWS patients are at risk for Wilms tumor development (DeBaun et al, 2002; Bliék et al, 2004; Brioude et al, 2013). An increased Wilms tumor risk is observed only in BWS patients with ICR1 gain of methylation and 11p15 uniparental disomy. In contrast, the tumor risk is lower in BWS with ICR2 loss of methylation and *CDKN1C* mutations.

Familial Wilms Tumor

As noted earlier, 1% to 2% of Wilms tumor patients have a family history of Wilms tumor (Breslow et al, 1996; Ruteshouser and Huff, 2004). Familial cases have an earlier age of onset and an increased frequency of bilateral disease. Two familial Wilms tumor genes have been localized (Ruteshouser and Huff, 2004). *FWT1* is located at 17q12-q21 and *FWT2* at 19q13.4 (Rahman et al, 1996; McDonald et al, 1998). Penetrance of these genes appears to be moderate, and these genes do not follow the typical tumor suppressor gene pattern of LOH (Strong, 2003).

Other Chromosomal Abnormalities

Mutations of the tumor suppressor gene *TP53* are frequently encountered genetic events in human cancer (Hollstein et al, 1991). *TP53* mutations are detected in up to 75% of Wilms tumor with anaplastic histology (AHWT) (Bardeesy et al, 1994). It has been suggested that a favorable-histology tumor may progress to an anaplastic tumor by acquiring a disruption of *TP53* function in a group of selected cells (Natrajan et al, 2007). The *TP53* mutations also have been correlated with advanced-stage disease (Malkin et al, 1990; Sredni et al, 2001), but indexing of p53 expression has not been shown to be an independent prognostic factor (Skotnicka-Klonowicz et al, 2001).

Loss of the long arm of chromosome 16 has been found in approximately 20% of Wilms tumors (Maw et al, 1992), suggesting the presence of a gene at 16q involved in the biology of Wilms tumor. Similarly, loss of the short arm of chromosome 1p has been found in approximately 10% of cases (Grundy et al, 1994). LOH at

1p and 16q is associated with an increased risk of tumor relapse and death (Grundy et al, 1994, 2005; Wittman et al, 2007). However, the prognostic significance of these features has been questioned (Bown et al, 2002). Confirming the usefulness of LOH of 16q and 1p to predict outcome was one of the major objectives of the fifth National Wilms Tumor Study (NWTs) (see later discussion). LOH of chromosome 11q is noted in approximately 20% of tumors. LOH of 11q is three to four times more frequent in anaplastic tumors (Wittman et al, 2007). There is a correlation with tumor recurrence and death, but only for tumors that have lost the entire long arm of chromosome 11.

Gain of 1q has also been identified to be another genetic change associated with outcome (Gratias et al, 2013; Segers et al, 2013). Gain of 1q has been noted in up to one fourth of favorable-histology Wilms tumors. It is important to note that 1q gain and LOH at 1p and 16q are not independent events. LOH at 1p and 16q often arises through chromosomal translocations that also result in 1q gain. After stratification for stage of disease, 1q gain was associated with a significantly increased risk of disease recurrence.

COG investigators have evaluated a large cohort of favorable-histology Wilms tumors for global gene expression patterns; *WT1*, *CTTNB1*, and *WTX* mutation; and 11p15 copy number and methylation patterns. They identified five subsets of tumors showing distinct differences in both their clinical and pathologic features. One unique subset was epithelial Wilms tumor in infants that lacked *WT1*, *CTTNB1*, and *WTX* mutations and nephrogenic rests (NRs), and none had recurrence of tumor. COG investigators hope to use this type of information to develop specific treatment strategies for different subsets of patients based on biology (Sredni et al, 2009; Gadd et al, 2012).

Screening

Screening with serial renal sonograms has been recommended in children at high risk for development of Wilms tumor. Review of most studies suggests that 3 to 4 months is the appropriate screening interval. Tumors detected by screening will usually be at a lower stage (Green et al, 1993; Choyke et al, 1999). No studies to date have demonstrated that early detection has improved patient survival. Early detection can provide an opportunity for nephron-sparing surgery, because these children are at an increased risk for bilateral disease. The smaller tumors found on screening studies are more amenable to renal-sparing surgery (Romao et al, 2012) (Fig. 155-6). It is recommended that screening be performed when a

condition has a Wilms tumor incidence of greater than 5% (Table 155-4) (Scott et al, 2006b). Screening of the contralateral kidney after nephrectomy for unilateral Wilms tumor is also recommended (D'Angio et al, 1993). Infants younger than 12 months found to have NRs in the resected kidney are at the greatest risk for metachronous tumors (Coppes et al, 1999). Ultrasound surveillance is performed from time of diagnosis until 5 years of age, with a frequency of every 3 to 4 months. Surveillance of patients who have BWS, Simpson-Golabi-Behmel syndrome, and familial Wilms histories should continue to 7 years (Scott et al, 2006b). CT or MRI should be performed if ultrasonography demonstrates a suspicious lesion. Nonmalignant renal lesions—for example, renal cysts—do occur at an increased rate in children with BWS, and recognition of these is important to avoid unnecessary nephrectomy when new lesions are identified on screening ultrasonography (Borer et al, 1999; Choyke et al, 1999).

An association between Wilms tumor and horseshoe kidney has been noted (Mesrobian et al, 1985). The diagnosis of horseshoe kidney can be missed on preoperative imaging because of the location of the tumor (Neville et al, 2002). Wilms tumor has been reported in patients with multicystic dysplastic kidney, but there is not sufficient evidence that this occurs at an incidence greater than for children with two normal kidneys (Narchi, 2005). There is an increased risk of müllerian duct anomalies in girls with Wilms tumor (Byrne and Nicholson, 2002). Approximately 10% of girls will have abnormalities such as duplication of the cervix or uterus or bicornuate uterus.

Pathology

Pathologists have made important contributions to the study of both the clinical behavior and the biology of Wilms tumor (Beckwith and Palmer, 1978; Weeks and Beckwith, 1987; Zuppan et al, 1991; Schmidt and Beckwith, 1995; Ravenel et al 2001; Vujanic and Sandstedt, 2002, 2010). Wilms tumor is characterized by tremendous histologic diversity, and classification of childhood tumors can be difficult. As noted in the earlier discussion, correlation of the pathologic findings with genetic events is improving our understanding of the development of Wilms tumor.

Favorable-Histology Wilms Tumor

Wilms tumor usually compresses the adjacent normal renal parenchyma, forming a pseudocapsule composed of compressed,

Figure 155-6. Small renal tumor found on serial screening. A, Ultrasound scan shows solid lesion just pushing out from the cortex. B, Computed tomography demonstrates that lesion is amenable to renal-sparing surgery.

TABLE 155-4 Syndromes Associated with Development of Wilms Tumor

SYNDROME	GENES	LOCUS	WILMS TUMOR RISK
WAGR	<i>WT1</i>	11p13	50%
Denys-Drash	<i>WT1</i>	11p13	50%
Frasier	<i>WT1</i>	11p13	5% to 10%
Beckwith-Wiedemann	<i>WT2</i>	IGF2, H19, p57, Klp2	5% to 10%
Familial Wilms tumor	<i>FWT1</i>	17q21	30%
	<i>FWT2</i>	19q13	
Perlman	Unknown		>20%
Mosaic variegated aneuploidy	<i>BUB1B</i>	15q15	>20%
Fanconi anemia D1	<i>BRCA2</i>	13q12.3	>20%
Simpson-Golabi-Behmel	<i>GPC3</i>	Xq26	10% (in males)
Li-Fraumeni	<i>P53</i>	17p13	Low
Neurofibromatosis	<i>NF1</i>	17q11	Low
Sotos	<i>NSD1</i>	5q35	Low
Trisomy 18	Unknown	18	Low

WAGR, Wilms tumor, aniridia, genital anomalies, mental retardation.

Figure 155-7. Typical Wilms tumor with blastemal, epithelial, and stromal components.

atrophic renal tissues. This intrarenal pseudocapsule can be helpful to distinguish Wilms tumor from NRs and other renal tumors. The texture of the tumors varies depending on the predominant histologic pattern. Many are soft and friable with necrotic or hemorrhagic areas frequently noted. This consistency increases the risk of intraoperative tumor rupture during primary nephrectomy. Most Wilms tumors are unicentric, but 12% are multicentric unilateral tumors (Breslow et al, 1988a). Extrarenal Wilms tumor arising in the retroperitoneum and elsewhere are rare and are thought to arise from displaced metanephric elements or mesonephric remnants. Derived from primitive metanephric blastema, Wilms tumor is characterized by tremendous histologic diversity (Beckwith and Palmer, 1978). In addition to expressing a variety of cell types found in a normal developing kidney, Wilms tumor often contains tissues such as skeletal muscle, cartilage, and squamous epithelium. These heterotopic cell types likely reflect the primitive developmental potential of metanephric blastema that is not expressed in normal nephrogenesis. "Classic" Wilms tumor is characterized by islands of compact undifferentiated blastema and the presence of variable epithelial differentiation in the form of embryonic tubules, rosettes, and glomeruloid structures separated by a significant stromal component (Fig. 155-7). The proportion of each of these

components varies from infrequent to abundant within and among individual tumors. Some Wilms tumors, however, are not triphasic, but demonstrate only biphasic or even monomorphous patterns, and the latter can present diagnostic difficulty (Schmidt and Beckwith, 1995). Wilms tumors with predominantly epithelial differentiation have a low degree of aggressiveness and the majority are stage I tumors (Beckwith et al, 1996; Vujanic and Sandstedt, 2010; Gadd et al, 2012). However, these tumors may be more resistant to therapy if they are at an advanced stage at presentation.

Anaplastic Wilms Tumor

Identification of tumors with unfavorable histologic features such as anaplasia was an important milestone accomplished by the inclusion of central pathologic review of the National Wilms Tumor Study Group (NWTSG) protocols (Beckwith and Palmer, 1978; Bonadio et al, 1985; Zuppan et al, 1988). It has allowed progressive use of adjuvant therapies in sequential studies based on the risk and response of the various pathologic tumor types. Anaplasia is characterized by the presence of three abnormalities: nuclear enlargement to three or more times the diameter of the adjacent cells, hyperchromasia of enlarged nuclei, and abnormal mitotic figures. Anaplasia is rarely seen in tumors of patients younger than 2 years at diagnosis (incidence about 2%), but its presence increases to a relatively stable incidence of about 13% in those older than 5 years (Bonadio et al, 1985; Green et al, 1994). Anaplasia is associated with resistance to chemotherapy. The presence of anaplasia has clearly been demonstrated to carry a poor prognosis even when the tumor is apparently confined to the kidney, stage I (Dome et al, 2006). Anaplasia has been further divided into focal and diffuse patterns to reflect further the different prognosis of anaplasia that is present throughout the kidney or in an extrarenal location (Faria et al, 1996). The later age at diagnosis and the general absence of anaplasia from NRs suggests that anaplasia develops from Wilms tumor cells that acquire additional genetic lesions (Williams et al, 2011).

Pathology after Preoperative Chemotherapy

The International Society of Paediatric Oncology (SIOP) studies have made some important observations on the histology of Wilms tumor after preoperative chemotherapy. Researchers performed an assessment of the tumor response after preoperative chemotherapy in terms of tumor volume and histology. The relative proportions

of histologic subtypes of Wilms tumor differ after preoperative chemotherapy when compared with those reported after primary surgical resection (Weirich et al, 2001). Stromal- and epithelial-predominant tumors are found more often after chemotherapy. These histologic subtypes may demonstrate a poor clinical response to therapy but have an excellent prognosis if the tumor is completely excised (Verschuur et al, 2010). The proportion of blastemal-predominant tumors is decreased after chemotherapy, indicating some response of this tumor type to the preoperative chemotherapy. However, patients with blastemal-predominant tumors after chemotherapy have a high rate of relapse (Reinhard et al, 2004b). Tumor progression during therapy occurred in 5% of patients enrolled in SIOP 93-01 (Ora et al, 2007). These patients were documented to have decreased OS.

SIOP classifies tumors with complete tumor necrosis after preoperative chemotherapy as “low-risk.” Children with stage I low-risk tumors after postchemotherapy nephrectomy receive no further chemotherapy (Boccon-Gibod et al, 2000). Tumors with diffuse anaplasia and blastemal predominance after chemotherapy are classified as “high-risk”; SIOP “intermediate-risk” tumors consist of all other histologies.

Nephrogenic Rests

More than one third of kidneys resected because of Wilms tumor contain precursor lesions known as *nephrogenic rests* (Beckwith et al, 1990; Beckwith, 1993). NRs have a varied natural history, and most do not form Wilms tumor. A rest can undergo maturation, sclerosis, involution, or complete disappearance. NRs have also been detected in 1% of kidneys in infants on postmortem examination—a much higher incidence than that of Wilms tumor. Hence, most apparently undergo involution (Beckwith, 1998).

NRs can be separated into two fundamentally distinct categories: *perilobar nephrogenic rests* (PLNRs) and *intralobar nephrogenic rests* (ILNRs) (Beckwith et al, 1990). These two types of NRs are distinguished by their location within the renal lobe. Relative position within the lobe is a direct reflection of the chronology of the embryologic development of the kidney. PLNRs are found only in the lobar periphery, which is elaborated late in embryogenesis, whereas ILNRs are found anywhere within the lobe, as well as the renal sinus and the wall of the pelvicaliceal system. Therefore, ILNRs are generally believed to be the result of earlier gestational aberrations (Beckwith, 1998). ILNRs are commonly stroma rich and intermingle with the adjacent renal parenchyma. PLNRs are usually subcortical, are sharply demarcated, and contain predominantly blastema and tubules. Of particular interest is the observation that PLNRs are usually found in children with BWS, linked to 11p15, whereas ILNRs are typically seen in children with aniridia, WAGR, and DDS or other features associated with *WT1*. The age at diagnosis is lower for Wilms tumor associated with *WT1* mutations and those tumors arising in association with ILNRs. These tumors have a stromal-predominant histology with varying degrees of rhabdomyogenesis (Fukuzawa et al, 2008).

Multiple rests in one kidney usually implies that NRs are present in the other kidney (Beckwith et al, 1990). Children younger than 12 months diagnosed with Wilms tumor who also have NRs, in particular PLNRs, have a markedly increased risk of developing contralateral disease and require frequent and regular surveillance for several years (Coppes et al, 1999). Surveillance is also recommended for those diagnosed after 12 months of age who have NRs (D'Angio et al, 1993). The occurrence of metachronous Wilms tumor in patients previously treated with conventional chemotherapeutic regimens suggests that NRs are not always eradicated.

NRs display a spectrum of appearances. Hyperplastic NRs can produce a renal mass that can be mistaken for a small Wilms tumor (Beckwith, 1998). Incisional biopsy of a hyperplastic rest is of little value in distinguishing this lesion from a Wilms tumor unless the interface between the rest and the normal kidney is included. Wilms tumor will have a pseudocapsule at the interface with the normal parenchyma, compressing the normal elements. The appearance of the lesion can provide some help in distinguishing between NR and

Figure 155-8. Typical appearance of diffuse hyperplastic perilobar nephrogenic rests with thick rind compressing the normal renal tissue centrally.

Wilms tumor. Wilms tumor will have a spheric shape, whereas hyperplastic rests will retain the appearance of the original rest and be more elliptical or lenticular in shape. MRI may be of some value in distinguishing between the two lesions, but this needs to be confirmed prospectively in large numbers of patients (Rohrschneider et al, 1998; Hoffer, 2005).

Nephroblastomatosis refers to the presence of multiple NRs. Diffuse overgrowth of PLNRs may produce a thick rind that enlarges the kidney but preserves its original shape (Fig. 155-8). Patients with nephroblastomatosis are prone to Wilms tumor development and bilateral lesions are common. Perlman and colleagues reviewed 52 cases of diffuse hyperplastic PLNRs reported to the NWTSG pathology center (Perlman et al, 2005). Wilms tumor developed in 23 patients at a median of 30 months. Of children receiving adjuvant therapy at diagnosis, 17 of 33 (52%) developed a Wilms tumor. There was an increased incidence of anaplasia noted in tumors that developed after chemotherapy in patients with nephroblastomatosis (Perlman et al, 2005).

Preoperative Evaluation and Staging

More than 90% of children with Wilms tumor have an asymptomatic abdominal mass discovered incidentally by a family member or physician. The mass may be extremely large relative to the size of the child and is not necessarily confined to one side. Approximately 20% of children with Wilms tumor have hematuria at diagnosis, and 25% will have hypertension at diagnosis. Gross hematuria warrants further evaluation to rule out tumor extension into the collecting system (Ritchey et al, 2008). Other symptoms include fever, anorexia, and weight loss in 10% of patients. Rarely, children may have acute abdominal pain from tumor rupture into the peritoneal cavity or bleeding within the tumor. Physical examination may reveal a firm, nontender mass that classically does not cross the midline.

Compression or invasion of adjacent structures may result in an atypical presentation. A persistent varicocele in the supine position or hepatomegaly may be reflective of inferior vena cava (IVC) obstruction from tumor thrombus. Atrial thrombus may manifest as hypertension or congestive heart failure. Such symptoms are found in less than 10% of patients with intracaval or atrial tumor extension (Ritchey et al, 1988; Shamberger et al, 2001). Occasionally, children with Wilms tumor have symptoms secondary to the production of bioactive substances by the tumor (Coppes, 1993). Hypertension can be caused by elevated plasma renin levels (Maas et al, 2007). This will usually resolve shortly after removal of the tumor. During the physical examination, it is important to assess

for signs of associated Wilms tumor syndromes such as aniridia, hemihypertrophy, and genitourinary anomalies.

Emergent operation is not necessary unless there is evidence of active bleeding or tumor rupture. The preoperative laboratory evaluation of a child with an abdominal mass should include a complete blood count, liver enzymes, and serum electrolytes, including blood urea nitrogen, creatinine, and calcium. Because as many as 8% of newly diagnosed patients with Wilms tumor will have acquired von Willebrand disease, coagulation studies should be considered (Coppes, 1993). This includes prothrombin time and partial thromboplastin time, which may be normal in the presence of von Willebrand disease. This defect can be corrected preoperatively with the administration of 1-desamino-8-D-arginine-vasopressin (DDAVP).

Imaging

A precise histologic diagnosis cannot be obtained on the preoperative imaging studies. All of the solid renal tumors of childhood have some common radiographic features including renal cell carcinoma (RCC) (Miniati et al, 2008; Smets, 2010). In the SIOP-9 study, 5.4% of patients in whom preoperative chemotherapy for Wilms tumor was commenced before diagnostic biopsy were found on nephrectomy to have renal malignancies other than Wilms tumor or benign renal conditions (Tournade et al, 2001). In the United Kingdom Children's Cancer Study Group (UKCCSG), 12% of renal tumors clinically and radiographically consistent with Wilms tumor were found to have some other diagnosis on biopsy (Vujanic et al, 2003). Other clinical parameters can provide some clues to the diagnosis. The development of a renal tumor in a child known to have aniridia, hemihypertrophy, or other syndromes associated with an increased incidence of nephroblastoma is most likely to be a Wilms tumor. Bilateral or multicentric tumors are more typical of Wilms tumor, but renal lymphoma can manifest in this fashion. Congenital mesoblastic nephroma (CMN) is the most likely diagnosis in a neonate with a renal mass. However, favorable-histology Wilms tumor and rhabdoid tumor of the kidney (RTK) can also manifest in the first few months of life (Ritchey et al, 1995; Leclair et al, 2005). The renal origin of the mass is usually apparent on CT, but it can be mistaken for neuroblastoma.

The clinical presentation—that is, as abdominal pain with tumor rupture—can create confusion regarding the preoperative diagnosis. In 2.5% of NWTSS-3 patients, there was an erroneous diagnosis before surgical exploration (Ritchey et al, 1992). Most of these children did not have any preoperative imaging studies performed, and this group of patients had an increased incidence of surgical complications. This emphasizes that defining the exact histology is not as important as establishing that the child has a solid renal tumor, allowing the surgeon to plan for a major cancer operation. Another important role of imaging is to confirm that the contralateral kidney is functioning before performing a nephrectomy.

Ultrasonography is often performed in children with an abdominal mass. This will demonstrate the solid nature of the lesion. Several studies have suggested that Doppler ultrasonography is particularly helpful to exclude intracaval tumor extension that occurs in 4% of Wilms tumor patients (Ritchey et al, 1988; Shamberger et al, 2001). MRI can reliably identify extension of tumor into the IVC (Schenk et al, 2008). A recent report from the COG demonstrated that CT was able to detect all clinically significant IVC tumor extension when compared with ultrasonography (Khanna et al, 2012).

All patients should undergo either CT of the abdomen and pelvis with oral and intravenous contrast or MRI of the abdomen and pelvis with gadolinium. MRI avoids radiation but typically requires anesthesia or sedation in young children. These imaging modalities can further define the extent of the lesion (Fig. 155-9) (Hoffer, 2005; Schenk et al, 2008). This allows improved preoperative planning by evaluating for extrarenal spread of disease, the relationship of the tumor to adjacent visceral structures, and the presence of synchronous tumors in the contralateral kidney. Routine exploration of the contralateral kidney at the time of nephrectomy is not necessary when preoperative imaging with thin slices on multi-

Figure 155-9. Computed tomography scan of a Wilms tumor that demonstrates preoperative rupture with perirenal hemorrhage.

tector helical CT scanners or MRI demonstrates a normal contralateral kidney (Ritchey et al, 2005).

However, the role of imaging studies in staging of the renal tumor continues to be defined. The COG found that CT has moderate specificity but poor sensitivity in the detection of preoperative tumor rupture (Khanna et al, 2013). Ascites beyond the cul-de-sac was most strongly associated with tumor rupture. If the preoperative imaging could accurately detect local extension of tumor beyond the renal capsule or into regional lymph nodes, it would obviate concerns regarding staging in patients treated with preoperative therapy. The local tumor burden (e.g., regional lymph node involvement) determines the intensity of the chemotherapy regimen and whether a child receives abdominal irradiation. Regional adenopathy can be identified on CT or MRI, but enlarged retroperitoneal benign lymph nodes are common in children, and correlation between pathologic findings and lymph node evaluation at surgical exploration in Wilms tumor patients has found significant false-positive and false-negative error rates (Othersen et al, 1990). It should not be expected that CT or MRI would have greater accuracy than visual inspection. Positron emission tomography (PET) has not been shown to have any advantages over conventional imaging modalities in preoperative assessment of Wilms tumor (Misch et al, 2008). Detection of extrarenal tumor extension into the perirenal fat and into adjacent structures is also problematic. Therefore determination of inoperability must be made at surgical exploration.

The lung is the most common site of distant metastasis in children with Wilms tumor. Preoperative chest CT with or without contrast is performed to rule out pulmonary metastases. The clinical significance of lung nodules detected on CT scan alone is controversial (Meisel et al, 1999; Owens et al, 2002; Grundy et al, 2012; Smets et al, 2012). CT will clearly detect more lesions than a standard chest radiograph, but not all of these lesions represent metastases (Ehrlich et al, 2006). Some reports have suggested that treatment of such patients with dactinomycin (AMD) and VCR is sufficient without the need for DOX or pulmonary radiation (Grundy et al, 2012; Smets et al, 2012). Others have found an increased risk of pulmonary relapse if more intensive treatment is not given (Owens et al, 2002).

Imaging surveillance after treatment of the primary tumor is recommended to detect tumor recurrence. COG studies advocate for periodic chest CT and either CT or MRI of the abdomen. However, some have begun to question the value of these studies and whether they will detect relapse early enough to improve survival (McHugh and Roebuck, 2014). Many patients will have clinical symptoms related to relapse before imaging detection. Omitting even the pelvic portion of the abdominal CT can significantly reduce the radiation exposure without compromising detection of relapse (Kaste et al, 2013).

TABLE 155-5 Staging System of the Children's Oncology Group

STAGE	
I	Tumor confined to the kidney and completely resected. The renal capsule is intact and the tumor was not ruptured before removal. No renal sinus extension. There is no residual tumor.
II	Extracapsular penetration, but tumor is completely resected. Renal sinus extension or extrarenal vessels may contain tumor thrombus or be infiltrated by tumor.
III	Residual nonhematogenous tumor confined to the abdomen: lymph node involvement, any tumor spillage, peritoneal implants, tumor beyond surgical margin either grossly or microscopically, or tumor not completely removed.
IV	Hematogenous metastases to lung, liver, bone, brain, and so on.
V	Bilateral renal involvement at diagnosis.

Clear cell sarcoma of the kidney (CCSK) and RCC have a propensity to metastasize to the skeleton (D'Angio et al, 1993; Indolfi et al, 2003). Skeletal surveys and bone scans are both recommended after the histologic diagnosis is confirmed (Feusner et al, 1990). Cranial CT or MRI is performed on all children with CCSK or with RTK, because both are associated with intracranial metastases (Weeks et al, 1989; Indolfi et al, 2003).

Staging

The most important determinants of outcome in children with Wilms tumor are the histopathology and tumor stage. Accurate staging of Wilms tumor allows treatment results to be evaluated and enables universal comparisons of outcomes. The current staging system used by the COG (Table 155-5) is based primarily on the surgical and histopathologic findings. Examination for extension through the capsule, residual disease, vascular involvement, and lymph node involvement are essential to properly assess the extent of the tumor at presentation.

Stage I tumors are limited to the kidney and are completely resected. However, evidence for tumor extension can be subtle. Tumor invasion of blood and lymphatic vessels in the renal sinus is the first sign of spread outside the kidney in stage II tumors (Weeks and Beckwith, 1987). Penetration through the renal capsule is the next most common finding of extrarenal spread. Clear demonstration of tumor cells in the perirenal fat is required to document capsular penetration. Any tumor spill leads to a stage III designation owing to the increased risk for local tumor recurrence (Shamberger et al, 1999; Ehrlich et al, 2013). For NWTS-5, the distribution by stage for patients with favorable-histology tumors was as follows: stage I, 24.9%; stage II, 29.9%; stage III, 30.6%; and stage IV, 14.5%. Patients with anaplastic tumors are more likely to have stage III or IV disease than those with favorable-histology tumors (Dome et al, 2006).

Prognostic Factors

As the treatment regimens for children with Wilms tumor have become more effective, the ability of retrospectively determined prognostic factors to predict outcomes has diminished. Traditional staging factors—for example, tumor size, histology, and lymph node metastases—relied on in the past to predict risk for tumor progression or relapse are now less able to stratify favorable-histology patients for treatment. Clinical cancer trials are now

incorporating biologic factors that predict tumor behavior to stratify patients for treatment.

Chromosomal Abnormalities. As noted earlier, LOH for a portion of chromosome 16q and/or 1p has been noted in 20% of Wilms tumors. This is associated with an increased risk for relapse (Grundy et al, 1994, 2005; Wittman et al, 2007; Messahel et al, 2009). This difference in outcome is independent of histology and stage. NWTS-5 patients with stage I or II favorable-histology tumors with LOH of either 1p or 16q had an increased risk of relapse and death in comparison with patients lacking LOH at either locus (Grundy et al, 2005). The risks of relapse and death for patients with stage III or IV favorable-histology tumors were increased only with LOH for both regions. Patients enrolled in the recently closed COG renal tumor protocols were selected for more intensive treatment if the tumor demonstrated LOH for 1p and 16q.

A number of other markers have been evaluated to predict tumor recurrence. High telomerase (a reverse transcriptase that maintains chromosome ends) activity has been found to be an unfavorable prognostic feature for several types of cancers. A case cohort study involving 291 patients with Wilms tumor confirmed the correlation between telomerase RNA expression and recurrence, and this was independent of tumor stage in multivariate analysis (Dome et al, 2005). A number of immunohistochemical markers have also been studied. It appears that most of the markers that are predictive of tumor progression are found in the blastemal component of the tumor (Routh et al, 2013; Ghanem et al, 2013). These markers will need to be evaluated in larger numbers of patients to determine their usefulness for risk stratification.

Cytokines. The growth of solid tumors is critically dependent on the induction of neovascularity by angiogenic cytokines. Vascular endothelial growth factor (VEGF) is an angiogenic cytokine detected with increased frequency and quantity in experimental and clinical specimens of Wilms tumor (Kayton et al, 1999; Karth et al, 2000). In experimental animals, lung metastases were far more likely to occur in animals with VEGF-positive tumors. Anti-VEGF therapy has been shown to suppress tumor growth in mice and can prevent development of metastases (Rowe et al, 2000; Frischer et al, 2004). Antiangiogenesis treatment would appear to be a promising adjunctive future treatment for patients with Wilms tumor.

Treatment

Surgical Considerations

The initial therapy for most children with Wilms tumor is radical nephrectomy. Nephrectomy should be performed via a transperitoneal approach. The surgeon is responsible for determining the extent of tumor. Accurate staging is essential for the subsequent determination of the need for radiation therapy and the appropriate chemotherapy regimen. Thorough exploration of the abdominal cavity is necessary to exclude local tumor extension, liver and nodal metastases, and peritoneal seeding. Exploration of the contralateral kidney is no longer mandated before nephrectomy if preoperative CT or MRI demonstrates a normal kidney (Ritchey et al, 2005). The renal vein and IVC are palpated to exclude intravascular tumor extension before vessel ligation. Wilms tumor extends into the IVC in approximately 6% of cases and may be clinically asymptomatic in more than 50% (Ritchey et al, 1988; Shamberger et al, 2001). The adrenal gland can be spared without increasing the risk for tumor spill or recurrence if it is not in close proximity to the tumor (Kieran et al, 2013a). Selective sampling of suspicious nodes is an essential component of local tumor staging. Formal retroperitoneal lymph node dissection is not recommended (Othersen et al, 1990; Shamberger et al, 1999). Extensive lymph node dissection, particularly above the renal hilum, can result in chylous ascites (Weiser et al, 2003). In a review of NWTS-4 and NWTS-5 patients, 12.5% of patients did not have lymph node sampling performed (Kieran et al, 2012). The likelihood of having a positive lymph node was greater if more than seven lymph nodes were sampled, but EFS was not improved with removal of more lymph nodes.

The other major responsibility when performing a nephrectomy for Wilms tumor is complete removal of the tumor without contamination of the operative field. Gentle handling of the tumor throughout the procedure is mandatory to avoid tumor spillage. A recent COG study reported intraoperative tumor spillage in 9.7% of patients undergoing primary nephrectomy (Gow et al, 2013). Multivariate analysis demonstrated that spillage was more common with right-sided tumors and larger tumors. Avoiding tumor spillage has a real impact on patient outcomes because these patients have an increase in local abdominal relapse (Shamberger et al, 1999). Shamberger and colleagues identified risk factors for local tumor recurrence as tumor spillage, unfavorable histology, incomplete tumor removal, and absence of any lymph node sampling (Shamberger et al, 1999). This study included both stage II and III disease. The risk of recurrence was highest in patients with stage II disease. More recent COG studies have treated all spill patients as having stage III disease. Review of these patients shows that the greatest risk of recurrence in stage III disease is associated with positive lymph nodes or residual disease (Ehrlich et al, 2013). Tumor spillage was not predictive of recurrence, likely because of the increased therapy currently given to these patients.

There have been several reports of laparoscopic nephrectomy for Wilms tumor. This is usually done in conjunction with preoperative chemotherapy and is likely more feasible after the tumor is reduced in size (Duarte et al, 2009). Experience with open nephrectomy after chemotherapy has shown that these tumors are less prone to tumor spillage (Powis et al, 2013). Although prechemotherapy laparoscopic nephrectomy has been reported, many more procedures will need to be performed to determine if there is an increased risk of tumor spillage, residual disease, or surgical complications (Barber et al, 2009).

Removing a large renal tumor in a small child is associated with some morbidity. NWT-4 patients undergoing primary nephrectomy had an 11% incidence of surgical complications (Ritchey et al, 1999). The most common complications encountered were hemorrhage and small bowel obstruction (Ritchey et al, 1992, 1993a, 1999). Factors that have been associated with an increased risk for surgical complications are higher tumor stage, tumor size greater than 10 cm, incorrect preoperative diagnosis, thoracoabdominal incision, intracaval tumor extension, and resection of other visceral organs.

Preoperative chemotherapy may influence surgical complication rates by producing tumor shrinkage. A recent report from the UKCCSG compared the complication rate for patients undergoing immediate nephrectomy versus delayed nephrectomy performed after 6 weeks of chemotherapy (Powis et al, 2013). They found significantly fewer complications in those undergoing delayed nephrectomy (1% vs. 5.8%). They also noted a much higher rate of tumor rupture or spill in those undergoing immediate nephrectomy (14.6% vs. 0%). This is similar to the rate of intraoperative tumor spill after immediate nephrectomy recently reported by the COG (Gow et al, 2013).

Cooperative Group Trials

Multiple randomized clinical trials have been conducted by the NWTSG, COG, SIOP, and UKCCSG to determine the appropriate role for each of the therapeutic modalities available. Patients are stratified into different treatment groups based on stage and pathology. The goals of these trials are to decrease the intensity of therapy for most patients in an effort to prevent late sequelae of treatment while maintaining excellent OS.

National Wilms Tumor Study Group and Children's Oncology Group. The NWTSG was formed in 1969 to study Wilms tumor. The early NWTSG studies, NWT-1 (1969 to 1973) and NWT-2 (1974 to 1978), showed that the combination of VCR and AMD was more effective than the use of either drug alone. The addition of DOX was found to improve survival for stage III and IV patients, and postoperative flank irradiation was unnecessary for stage I patients (D'Angio et al, 1976, 1981). A major achievement of the early trials was identification of prognostic factors that allowed

stratification of patients into high-risk and low-risk treatment groups. Patients with positive lymph nodes and diffuse tumor spill were found to be at increased risk of abdominal relapse and therefore considered stage III and given postoperative irradiation. One of the most important findings was the identification of the unfavorable histologic features that have a very adverse impact on survival.

NWT-3 (1979 to 1986) demonstrated that stage I and II patients could be treated with 18 weeks of AMD and VCR without irradiation (D'Angio et al, 1989). For stage III favorable-histology disease, 10.8 Gy of abdominal irradiation was shown to be as effective as 20 Gy in preventing abdominal relapse if DOX was added to VCR and AMD. NWT-4 (1987 to 1994) proved that treatment durations of 6 months produced comparable outcomes to 15 months of therapy for patients with stage II to IV favorable-histology tumors (Green et al, 1998). The NWTSG has assessed the impact of postoperative irradiation on flank recurrence and survival (Breslow et al, 2006a; Kalapurakal et al, 2010; Green et al, 2014). The investigators found that abdominal recurrence rates after tumor spillage were significantly higher among patients treated with two- or three-drug chemotherapy without radiation therapy. Irradiation with 10 Gy appeared to be successful in reducing tumor recurrence rates after tumor spillage, and 20 Gy even more so. Although radiation did decrease the incidence of flank recurrence, there was only an increase in OS for stage II patients with tumor spillage. This was attributed to a lower postrecurrence mortality rate in unirradiated patients. The overall risk for relapse is low in stage II favorable-histology disease with spillage, and one must weigh the risks of late effects of intensified treatment versus benefit of decreased relapse (Green et al, 2014).

NWT-5 (1995 to 2003) was a single-arm therapeutic trial. One of the major aims of the trial was to confirm the usefulness of LOH for chromosomes 16q and 1p to predict increased risk of tumor relapse and death (Grundy et al, 2005). Another objective was to evaluate the efficacy of treatment regimens for AHWT. Stage I patients with anaplastic tumors were treated with AMD and VCR, but this resulted in a low 4-year EFS of 69.5% (Dome et al, 2006). A new intensified chemotherapy regimen used for patients with stage II to IV diffuse anaplasia did not result in an improved survival.

In NWT-5, children younger than 2 years with stage I favorable-histology tumors weighing less than 550 g were defined as having very-low-risk Wilms tumor (VLRWT) and did not receive chemotherapy after nephrectomy. This portion of the study was closed early when the number of tumor relapses exceeded the limit allowed by the design of the study (Green et al, 2001a). A recent long-term review of this cohort was completed, comparing the outcomes with those of similar patients treated with postoperative AMD and VCR (Shamberger et al, 2010). The 5-year EFS for surgery alone was 84% compared with 97% for the treated group, but the 5-year OS was equivalent between the two groups at 98% and 99%, respectively ($P = .70$). There is a trade-off between more intensive therapy and the potential long-term sequelae for the 16% of children who relapse versus the avoidance of any postoperative chemotherapy in the majority. As noted earlier, COG investigators hope to use biologic prognostic factors to select patients who do not require adjuvant therapy. All VLRWT patients registered in NWT-5 who did not receive adjuvant chemotherapy were analyzed for LOH at 11p15 and for *WT1* mutation. LOH, as determined by 11p15 methylation analysis, was significantly associated with relapse in VLRWT, as were *WT1* abnormalities (Perlman et al, 2011). If these results are validated in an independent cohort of patients, it would be worthwhile to conduct a clinical trial that uses molecular genetic factors rather than the arbitrarily defined clinical factors of patient age and tumor weight to identify patients with stage I favorable-histology Wilms tumor who do not require adjuvant therapy. It is anticipated that such a trial would expand the number of patients who would be candidates to be treated with surgery only.

Relapse. A uniform approach for the treatment of tumor relapse was used in NWT-5. Patients with relapsed Wilms tumor may be divided into risk groups according to OS rates after salvage therapy (Spreafico et al, 2009). Children with nonanaplastic Wilms tumor

who relapse after therapy with only VCR and/or AMD are considered at standard risk and have survival rates in the 70% to 80% range (Green et al, 2007). Patients with nonanaplastic Wilms tumor who relapse after therapy with three or more agents are defined as having high risk and have survival rates in the 40% to 50% range (Malagolowkin et al, 2008). The very-high-risk group includes recurrent anaplastic or blastemal-type Wilms tumor; these patients have survival rates in the 10% range (Reinhard et al, 2008).

The first generation of COG studies (2006 to 2013) grouped patients by risk for recurrence (very low, low, standard, and high). The COG again examined the role of surgery-only treatment for patients with stage I favorable-histology Wilms tumor in which the tumor and kidney weighed less than 550 g and patient age was below 2 years. Children with stage I or II favorable-histology Wilms tumor and LOH of 1p and 16q were treated with VCR, AMD, and DOX without radiotherapy. Patients with stage III favorable-histology Wilms tumor disease without LOH of 1p and 16q were treated with VCR, AMD, and DOX and irradiation of the flank or abdomen. The COG evaluated a response-based approach for management of children with pulmonary metastases. Those with resolution of the pulmonary lesions on chest CT after 6 weeks of chemotherapy were continued on treatment with VCR, AMD, and DOX. Patients who did not have resolution of the pulmonary lesions by week 6 received more intensive chemotherapy and pulmonary irradiation. Children with stage I to III focal AHWI and stage I diffuse AHWI were treated with AMD, VCR, DOX, and abdominal irradiation. Patients with stage II, III, or IV (no measurable disease) diffuse AHWI, stage IV focal AHWI, stage IV clear cell sarcoma, or stage I to III malignant rhabdoid tumor were treated with a new chemotherapy regimen to try to improve OS. All of the COG studies are closed to patient accrual with the exception of the renal-sparing study (see later).

Wilms tumor occasionally occurs in adults. Earlier reports suggested that the outcome for adults with Wilms tumor was poor and that they require more intensive therapy (Arrigo et al, 1990). More recent reviews of adult patients with favorable-histology Wilms tumor have found improved survival compared with prior reports (Kalapurakal et al, 2004a; Reinhard et al, 2004a; Ali et al, 2012). The recommendation is that adult patients receive stage-appropriate combined-modality therapy.

International Society of Paediatric Oncology. In the randomized clinical trials conducted by SIOP, preoperative therapy is given before surgery. This approach usually results in tumor shrinkage (Fig. 155-10), reducing the risk of intraoperative rupture or spill (Lemerle et al, 1976). A greater number of patients have post-

chemotherapy stage I tumors as a result of disappearance of micro-metastases after neoadjuvant therapy. This was thought to be a significant advantage in terms of decreasing morbidity of treatment, particularly the late effects of radiotherapy.

Early SIOP studies evaluated prenephrectomy radiation therapy (Lemerle et al, 1976). SIOP-5 (1976 to 1980) showed that use of 4 weeks of AMD and VCR was as effective as prenephrectomy radiation therapy in avoiding surgical tumor rupture and increasing the proportion of patients with low-stage disease (Lemerle et al, 1983). SIOP-6 (1980 to 1987) demonstrated that patients with post-chemotherapy stage I disease can safely be treated with 18 weeks of AMD and VCR (Tournade et al, 1993). However, patients with post-chemotherapy stage II tumors and negative lymph nodes were found to have a higher rate of abdominal relapse if postoperative irradiation was omitted (Tournade et al, 1993). An anthracycline was subsequently added for treatment of these children. SIOP-6 confirmed the need for a three-drug chemotherapy regimen after nephrectomy for patients with postchemotherapy stage II lymph node positive and stage III tumors. SIOP-9 (1987 to 1993) demonstrated that the relapse rate for stage II patients with negative lymph nodes without radiation therapy was reduced with epirubicin (Tournade et al, 2001). This study also demonstrated that treatment with VCR and AMD for 4 weeks versus 8 weeks had comparable rates of stage distribution and tumor shrinkage in patients with stage I to III disease. The majority of tumor shrinkage was noted in the first 4 weeks of therapy. Radiotherapy was limited to patients with stage II node-positive and stage III disease, resulting in 18% of patients being irradiated (Graf et al, 2000). There were 59 children with stage I to -IV tumors who had complete tumor necrosis induced by chemotherapy, and 98% of these children had no evidence of disease at 5 years (Boccon-Gibod et al, 2000).

The SIOP 93-01 study (1993 to 2001) evaluated a reduction in postoperative therapy for patients with stage I intermediate risk and anaplastic Wilms tumor (de Kraker et al, 2004; Reinhard et al, 2004b; Graf et al, 2012). Patients were randomized to receive either 4 or 18 weeks of postoperative chemotherapy with AMD and VCR. Two-year EFS was 91.4% after 4 weeks and 88.8% after 18 weeks of therapy, demonstrating that survival can be maintained while shortening the duration of postnephrectomy therapy. Patients with stage II or III disease with low- or intermediate-risk histology received 4 weeks of AMD and VCR before surgery. Postoperative chemotherapy consisted of AMD, VCR, and epirubicin/DOX for 27 weeks. Flank or whole-abdomen irradiation was given for stage III disease. With a median follow-up of 8 years, 5-year EFS was 90% and OS was 95%. Patients with blastemal-type histology had a worse prognosis,

Figure 155-10. A, Computed tomography scan of a Wilms tumor that was pretreated with chemotherapy. B, After 6 weeks of chemotherapy, the tumor is much smaller.

with 62% EFS at 5 years. They comprised only 10% of patients but contributed to one third of the relapses and deaths. The other important prognostic factors were a large tumor volume at surgery and stage III disease.

The SIOP 2001 study asked whether patients with stage II or III intermediate-risk histology Wilms tumors could be safely treated without an anthracycline. Data from SIOP 93-01 had suggested that survival was not adversely affected when nonviable tumor was identified in the renal sinus and/or perirenal fat after preoperative chemotherapy (Vujanic et al, 2009). A total of 583 patients were randomized from 2001 to 2009 (Pritchard-Jones et al, 2011). For stage II or stage III intermediate-risk histology Wilms tumor, there was no significant disadvantage in removing DOX from postoperative chemotherapy. The SIOP group now recommends 6 months only of VCR and AMD rather than a three-drug regimen including DOX. This will significantly reduce the number of children receiving this cardiotoxic drug.

United Kingdom Children's Cancer Study Group. The UKCCSG has conducted several trials using prenephrectomy chemotherapy, but, unlike SIOP, this group performed biopsy before treatment (Pritchard et al, 1995; Mitchell et al, 2000; Pritchard-Jones et al, 2003). This is done to avoid giving chemotherapy to infants and children with benign tumors, which account for 1% of lesions thought to be Wilms tumor on imaging studies (Tournade et al, 2001). The other reason to perform biopsy is to avoid giving inappropriate chemotherapy to non-Wilms tumors, which often require more intensive therapy. The UKW3 trial noted a 12% incidence of non-Wilms tumors in patients with the typical features of Wilms tumor on imaging studies (Vujanic et al, 2003). The UKW1 and UKW2 studies evaluated the single agent VCR for treatment of stage I favorable-histology tumors (Pritchard et al, 1995; Mitchell et al, 2000). The OS of 96% compares well with two-drug chemotherapy, but age greater than 4 years was considered an adverse prognostic factor (Pritchard-Jones et al, 2003).

The UKW3 trial randomly assigned patients to either immediate surgery or to 6 weeks of preoperative chemotherapy and then delayed surgery (Mitchell et al, 2006). EFS and OS at 5 years were similar in the two groups. Around 20% of survivors avoided treatment with DOX or radiotherapy as a result of favorable stage distribution after preoperative therapy. The researchers concluded, like the SIOP group, that all children with nonmetastatic Wilms tumor should receive chemotherapy before tumor resection.

Preoperative Chemotherapy (Children's Oncology Group Recommendations)

On the COG renal tumor protocols, treatment is dependent on surgical and pathologic staging after immediate nephrectomy. There are, however, some situations wherein preoperative chemotherapy is recommended. These include children for whom renal-sparing surgery is planned (Blute et al, 1987), tumors inoperable at surgical exploration (Ritchey et al, 1994), and tumor extension into the IVC above the hepatic veins (Ritchey et al, 1993b; Shamberger et al, 2001; Szavay et al, 2004). The last two conditions are associated with an increased risk for surgical complications if primary nephrectomy is performed (Ritchey et al, 1992).

Inoperable Tumors. The surgeon, not the oncologist or radiotherapist, must make the determination that a tumor is inoperable. This decision should not be based on preoperative imaging studies, which can overestimate local tumor extension. As noted earlier, not all renal masses in children represent Wilms tumor (Vujanic et al, 2003; Reinhard et al, 2004b). If the tumor is found to be unresectable, pretreatment with chemotherapy almost always reduces the bulk of the tumor and renders it resectable (Ritchey et al, 1994; Grundy et al, 2004). Patients who are staged with imaging studies alone and receive preoperative chemotherapy before nephrectomy are also at risk for understaging (Tournade et al, 1993). A patient determined to have an inoperable tumor should be considered to have stage III disease and should be treated accordingly (Ritchey et al, 1994).

Repeat imaging is performed after 6 weeks of chemotherapy. Experience in SIOP has shown that the majority of reduction (48%) in tumor volume occurs in the first 4 weeks of therapy (Tournade et al, 2001) but that reduction extends out through 8 weeks (62%). After there has been adequate shrinkage of the tumor, definitive resection can usually be completed. A clinically good response (by imaging) is usually associated with a pathologically good response in terms of regressive histologic changes (Zuppan et al, 1991; Weirich et al, 2001). The converse is not always true. The distribution of histologic subtypes is different after preoperative chemotherapy compared with primary surgery, with differentiation of the tumor occurring after chemotherapy. Stromal- and epithelial-predominant tumors are found more often after treatment with preoperative chemotherapy. These histologic subtypes may demonstrate a poor clinical response to therapy but have an excellent prognosis if the tumor is completely excised. Patients with progressive disease have a poor prognosis, and these patients will require treatment with a more intensive chemotherapeutic regimen (Ritchey et al, 1994; Ora et al, 2007).

Bilateral Wilms Tumors. Synchronous bilateral Wilms tumors occur in 5% to 7% of children with Wilms tumor (Blute et al, 1987; Coppes et al, 1989; Montgomery et al, 1991). Children with bilateral tumors should not undergo initial radical nephrectomy. These children should receive preoperative chemotherapy with the goal of tumor shrinkage and renal-sparing surgery (Blute et al, 1987; Coppes et al, 1989; Kumar et al, 1998; Hamilton et al, 2011). Preservation of renal tissue is important to decrease the incidence of renal failure, which approaches 15%, at 15 years after treatment in patients with bilateral Wilms tumor (Ritchey et al, 1996; Breslow et al, 2005). The most common cause for renal failure was the need for bilateral nephrectomy for persistent or recurrent tumor in the remaining kidney after initial nephrectomy. Complete nephrectomy can be avoided in the majority of patients if a careful protocol is followed and the surgery is performed by surgeons experienced in renal-sparing techniques (Davidoff et al, 2008; Fuchs et al, 2011).

The current COG protocol for patients with bilateral Wilms tumor recommends 6 weeks of chemotherapy before surgery. Biopsy is not needed if the radiographic picture is consistent with Wilms tumor. Tumor response is assessed after 6 weeks with CT or MRI to determine the reduction in tumor volume and feasibility of partial resection. Patients with tumors amenable to renal-sparing procedures can proceed with surgery. Imaging cannot, however, predict the histology of the tumor based on changes in volume of the tumor after chemotherapy (Weirich et al, 2001; Olsen et al, 2004). Tumors not responding to therapy require bilateral open biopsy to determine histology. Open biopsies are recommended because they are more accurate than percutaneous needle biopsies when assessing for anaplasia, and bilateral biopsies are recommended because anaplasia is found to be discordant between the two kidneys in 83% of children (Hamilton et al, 2006). Failure to achieve a reduction in volume is likely a result of tumor differentiation (Fig. 155-11) (Weirich et al, 2001; Anderson et al, 2002; Shamberger et al, 2006). Differentiated tumors may show a poor clinical response to therapy, but they have an excellent prognosis if the tumor is completely excised. If renal-sparing surgery is not feasible, additional chemotherapy is then given based on the biopsy findings, but all patients should proceed to surgical resection within 12 weeks of starting therapy. Continuing treatment beyond 12 weeks will not likely provide any additional reduction in tumor burden.

At the time of second-look surgery, partial nephrectomy or wedge excision of the tumor is preferred with an attempt to achieve negative margins. The kidney with the lower tumor burden is addressed first. Tumor enucleation may be considered in lieu of a formal partial nephrectomy. This is often needed for large centrally located tumors when removal of a margin of renal tissue would compromise the vascular supply to the kidney (Cozzi et al, 1996; Horwitz et al, 1996). The concern is that enucleation will be more likely to result in positive surgical margins. For favorable-histology tumors, adjuvant therapy may still achieve a good outcome (Cozzi et al, 1996; Horwitz et al, 1996; Davidoff et al, 2008). However, if

Figure 155-11. Patient with bilateral tumors who was treated with chemotherapy. **A**, Computed tomography (CT) before treatment. **B**, CT after 12 weeks of chemotherapy, revealing only minimal decrease in the size of the tumors. Bilateral partial nephrectomies were performed, revealing mature tumor elements with rhabdomyoblastic differentiation.

Figure 155-12. Postoperative image from patient shown in [Figure 155-11](#) demonstrates that the kidneys have near-normal volume after resection of the bilateral tumors.

there is anaplasia in the resected specimen, a positive margin will adversely affect survival and requires additional resection. Even when large bilateral masses remain after initial chemotherapy, a high percentage of children can be successfully managed with renal-sparing surgery ([Davidoff et al, 2008](#)). It is easy to underestimate the amount of renal parenchyma that can be salvaged as a result of compression by the tumor; therefore nephron-sparing surgery should be considered in all patients ([Fig. 155-12](#)). One concern regarding enucleation of large centrally located tumors is the potential for positive surgical margins. Kieran and colleagues reported a 23% incidence of positive surgical margins in a cohort of 21 patients with bilateral Wilms tumor undergoing renal-sparing surgery ([Kieran et al, 2013b](#)). They did not demonstrate an increased risk of local recurrence, but this was a small number of patients, with all receiving 10.5-Gy flank radiation.

Radical nephrectomy may be needed in a kidney with extensive tumor involvement. Bilateral nephrectomies and dialysis are rarely required when the tumors fail to respond to chemotherapy and radiation therapy. This is the most common cause of renal failure in patients with bilateral Wilms tumor ([Ritchey et al, 1996](#)). Fortunately, anephric patients can still be administered chemotherapy with some modifications ([Feusner et al, 2008](#)). The recommended interval between successful completion of treatment of the Wilms

tumor and renal transplantation varies ([Penn, 1979](#); [Kist-van Holthe et al, 2005](#)). Some advocate a waiting period of 2 years to ensure that the patient does not develop metastatic disease; others have found that a 1-year interval is sufficient ([Gregoriev et al, 2012](#)). Patients who develop renal failure after renal-sparing surgery should have removal of the remaining renal tissue before transplant to prevent tumor recurrence after starting immunosuppression ([Kubiak et al, 2004](#)).

All patients treated for bilateral Wilms tumor require close long-term follow-up. SIOP investigators noted that late relapses have occurred in patients with bilateral Wilms tumor more than 4 years after treatment and recommended long-term follow-up ([Coppes et al, 1989](#)). These patients should also have frequent assessment of renal function, urine protein, and blood pressure.

Partial Nephrectomy for Unilateral Tumors. Several centers have explored the role of parenchymal-sparing procedures in children with unilateral Wilms tumors ([McLorie et al, 1991](#); [Cozzi et al, 1996](#); [Moorman-Voestermans et al, 1998](#); [Haecker et al, 2003](#); [Linni et al, 2003](#); [Zani et al, 2005](#)). The primary motivation for this approach is concern about late occurrence of renal dysfunction after unilateral nephrectomy. However, the incidence of renal failure after nephrectomy for most children with unilateral Wilms tumor is low, 0.6% at 20 years after treatment ([Breslow et al, 2005](#); [Lange et al, 2011](#)). The risk of renal failure is higher for patients with genitourinary anomalies, DDS, and WAGR. As noted earlier, this is a result of mutation of *WT1*, which is necessary for normal renal development. Syndromic patients are more likely to have smaller tumors identified on screening studies that are more amenable to renal-sparing surgery ([Romao et al, 2012](#)).

Most Wilms tumors are too large at diagnosis to allow partial nephrectomy. After preoperative chemotherapy, partial nephrectomy can be performed in 10% to 15% of patients. Only the occasional child with Wilms tumor will have a lesion small enough to allow partial nephrectomy at diagnosis—for example, tumors detected on screening studies for Beckwith-Wiedemann syndrome and aniridia (see [Fig. 155-6](#)). As noted earlier, there are concerns regarding staging after chemotherapy, requiring some patients to receive added therapy to prevent local recurrence. Another concern is the increased risk for local recurrence after partial nephrectomy ([Horwitz et al, 1996](#); [Haecker et al, 2003](#)). Patients who develop intra-abdominal relapse have a markedly decreased survival ([Shamberger et al, 1999](#)).

The COG is conducting a renal-sparing protocol for select patients with unilateral Wilms tumors known to be at risk for bilateral disease or at increased risk for renal failure. These patients

are managed with a strict surgical protocol to minimize risk for residual disease (Cozzi et al, 2004). The lesion should be completely excised with a margin of normal renal parenchyma. These patients should not undergo partial nephrectomy if the tumor cannot be removed at stage I. Patients with high-risk histologic patterns such as anaplasia or persistent blastemal-predominant tumor after chemotherapy should be treated with complete nephrectomy because these tumors have resistance to chemotherapy (Reinhard et al, 2008).

Late Effects of Treatment

Numerous organ systems are subject to the late sequelae of anticancer therapy. Clinicians must be aware of the spectrum of problems that face children as they grow into adulthood. Our understanding of late effects in Wilms tumor survivors has been advanced through two large studies. The Childhood Cancer Survivor Study (CCSS) is a retrospectively ascertained cohort of 20,346 childhood cancer survivors diagnosed from 1970 to 1986. The CCSS reported a cumulative incidence of 65% for all chronic health conditions in Wilms tumor survivors at 25 years after completion of therapy (Termuhlen et al, 2011). The cumulative incidence of severe (grades 3 or 4) chronic health conditions was 24% (Termuhlen et al, 2011). The NWTSG Late Effects Study followed patients treated in NWTSG-1 to NWTSG-5. Despite the greatly improved therapy for Wilms tumor over time, the NWTSG Late Effects Study showed that survivors remain at elevated risk for death compared with the general population for many years after their original diagnosis (Cotton et al, 2009).

Fertility and Pregnancy

Gonadal radiation can produce hypogonadism and temporary azoospermia in boys (Kinsella et al, 1989). The severity of damage is radiation dose dependent. The Leydig cells are more radioresistant than the germ cells, but higher doses can produce damage resulting in inadequate production of testosterone. This can result in delayed sexual maturation. Chemotherapeutic agents can also adversely affect testicular function (Mustieles et al, 1995). Pelvic irradiation and exposure to alkylating agents are risk factors for ovarian failure and premature menopause in female Wilms tumor survivors (Green et al, 2009). Very few pregnancies have been reported in patients who received whole abdominal radiation therapy (Green et al, 2010). Pregnancy complications were evaluated extensively through the NWTSG. The offspring of irradiated female patients are at risk for low birth weights and premature birth. Radiation portals that include the pelvis and doses exceeding 20 Gy increase the risk of miscarriage (Kalapurakal et al, 2004b).

Second Malignancies

An increased incidence of second malignant neoplasms has been noted in children treated for Wilms tumor. There is a 1% cumulative incidence at 10 years post-diagnosis, and a rising incidence thereafter (Breslow et al, 1988b; Taylor et al, 2008; Breslow et al, 2010). One of the greatest risk factors is prior irradiation, and most tumors occur in the radiation field (Breslow et al, 1988b; Bassal et al, 2006; Taylor et al, 2008). The incidence of leukemia is highest during the first 5 years after Wilms tumor treatment. The incidence of solid tumors increases fivefold from age 15 years to age 40 years.

Cardiac Effects

The risk of cardiotoxicity in Wilms tumor survivors has been carefully studied. In a review of patients entered in NWTSG-1, NWTSG-2, NWTSG-3, and NWTSG-4, the frequency of congestive heart failure was 4.4% among DOX-treated patients who received this drug as part of their initial chemotherapy regimen (Green et al, 2001b). The risk was increased if the patient received whole-lung or left-flank irradiation. Of note, only one patient with congestive heart failure received a DOX cumulative dose below 150 mg/m², which is used in contemporary North American treatment regimens. However, subclini-

cal cardiotoxicity was not assessed, and it is possible that clinical effects with modern regimens will become apparent with longer follow-up.

OTHER RENAL TUMORS

Clear Cell Sarcoma of the Kidney

CCSK accounts for 3% of renal tumors reported to the NWTSG. The tumor derives its name from the clear cytoplasm of the predominant cell type (Schmidt and Beckwith, 1995). **Important predictors of improved survival are lower stage, younger age at diagnosis, treatment with DOX, and absence of tumor necrosis (Argani et al, 2000).** The addition of DOX improved both OS and relapse-free survival (D'Angio et al, 1989; Argani et al, 2000; Seibel et al, 2004). Patients with stage I tumors (using the current criteria of absence of renal sinus invasion) had a 98% survival rate. Unlike anaplastic Wilms tumor, even stage I CCSK lesions are associated with increased rates of relapse and require postoperative irradiation. Long-term follow-up of CCSK patients is needed because 30% of relapses occurred more than 3 years after diagnosis and some as late as 10 years. Unlike Wilms tumor, **CCSK is associated with bone and brain metastases.** Bilateral involvement has thus far not been reported, nor has the presence of Wilms tumor-associated congenital anomalies such as aniridia or hemihypertrophy. Patients with CCSK were treated in NWTSG-5 with a regimen combining VCR, DOX, cyclophosphamide, and etoposide in an attempt to further improve the survival of this high-risk group. However, outcomes for patients with CCSK treated in NWTSG-5 were similar to those seen in NWTSG-4 (5-year relapse-free survival and OS of 79% and 89%, respectively) (Seibel et al, 2006). Stage was found to be highly predictive of outcome; 5-year relapse-free survival rates for stages I, II, III, and IV in NWTSG-5 were 100%, 87%, 74%, and 36%, respectively. Similar outcomes have been reported by SIOP investigators (Furtwangler et al, 2013).

Rhabdoid Tumor of the Kidney

RTK is the most aggressive and lethal childhood renal tumor and accounts for 2% of renal tumors. RTK and CCSK both occur in renal and extrarenal locations, suggesting an origin from a non-organ-specific mesenchymal cell. These tumors are characterized by loss of function of the *SMARCB1/INI1/SNF5/BAF47* gene in chromosome band 22q11.2 (Biegel et al, 1999). Consistent with its role as a tumor suppressor gene, tumors arise after inactivation of both alleles of *SMARCB1*. Germline alterations of the *SMARCB1* gene are found in one third of the patients (Eaton et al, 2011). Germline mutations of *INI1* have been identified in renal rhabdoid tumors. Staining for the products of the *INI1* gene can be useful because RTK is consistently negative (Hoot et al, 2004).

Typical clinical features include early age of diagnosis (median age below 16 months), advanced stage, resistance to chemotherapy, and high mortality (Amar et al, 2001; Tomlinson et al, 2005). Younger age at diagnosis is an adverse prognostic factor. RTK is distinguished by its propensity to metastasize to the brain (D'Angio et al, 1993).

Congenital Mesoblastic Nephroma

CMN is the most common renal tumor in infants, with a mean age at diagnosis of 3.5 months (Howell et al, 1982; van den Heuvel-Eibrink et al, 2008). This is the most common renal tumor diagnosed on antenatal ultrasonography (Leclair et al, 2005). CMN is a very firm tumor on gross examination, and the cut surface has the yellowish gray trabeculated appearance of a leiomyoma. There are three histologic subtypes: classic, cellular, and mixed (showing areas of both classic and cellular). The classic subtype, characterized by interlacing sheets of bland spindle cells, resembles infantile fibromatosis. The cellular variant, with a solid sheetlike growth pattern and frequent mitoses, is virtually identical histologically to congenital fibrosarcoma (Beckwith, 1986; Joshi et al, 1986; Gormley

et al, 1989). Both tumors have a similar translocation that fuses the *ETV6 (TEL)* gene from 12p13 with the 15q25 neurotrophin-3 receptor gene, *NTRK3* (Argani et al 1998). In CMN, tumor induction is postulated to occur at a time when the multipotent blastema is predominately stromagenic (Snyder et al, 1981; Tomlinson et al, 1992). *WT1* is not expressed in CMN (Tomlinson et al, 1992).

The most important aspect of CMN is the usually excellent outcome with radical surgery only (Howell et al, 1982). The tumor can extend into the hilar or perirenal soft tissue; therefore complete surgical resection is important (Beckwith, 1986). Local recurrence and metastasis can occur, particularly with the cellular variant of CMN (Joshi et al, 1986; Gormley et al, 1989; Fitchey et al, 2003). The risk of recurrence is thought to be less in children younger than 3 months at diagnosis, but metastases have been reported in a few infants (Heidelberger et al, 1993). Neither chemotherapy nor radiation therapy is routinely recommended (Howell et al, 1982), but consideration for adjuvant treatment should be given to patients with cellular variants that are incompletely resected (Gormley et al, 1989). There are reports demonstrating response of both inoperable and recurrent tumors to chemotherapy (Loeb et al, 2002; McCahon et al, 2003).

Solitary Multilocular Cyst and Cystic Partially Differentiated Nephroblastoma

Solitary multilocular cyst, or multilocular cystic nephroma, is an uncommon, benign renal tumor. Fifty percent of multilocular cysts are found in young children, usually boys. The second peak incidence occurs in young adult women (Eble and Bonsib, 1998; Luthile et al, 2007). Although the majority of cases of multilocular cystic renal disease have been unilateral, there are rare reports of bilateral cases (Ferrer and McKenna, 1994). The gross appearance of the tumor is its most distinguishing feature. The cut surfaces reveal a well encapsulated multilocular tumor composed of varying sized cysts compressing the surrounding renal parenchyma. This tumor is distinguished by the finding of only mature cell types within the septa of the cyst wall. Multilocular cystic nephroma is cured by nephrectomy, but recurrence has occurred following incomplete excision by partial nephrectomy. If partial nephrectomy is considered, frozen section is indicated to exclude cystic, partially differentiated nephroblastoma or clear cell sarcoma, which can occasionally have a similar appearance.

Another entity reported in the literature with similar features is cystic partially differentiated nephroblastoma (CPDN). The majority of these lesions occur in the first 2 years of life (Joshi and Beckwith, 1989; Blakely et al, 2003; Luthile et al, 2007). Eble and Bonsib recommend that multilocular cystic nephroma and CPDN be considered the same entity (Eble and Bonsib, 1998). They are indistinguishable radiographically. Histologic examination reveals that blastemal cells or NRs may be found in the septa of both tumors. Surgery is curative in almost all patients, with recurrence the result of incomplete resection (Eble and Bonsib, 1998; Blakely et al, 2003). In a review of 21 children with CPDN reported to the NWTSG, there was 100% survival. Eight were treated with surgery alone (Blakely et al, 2003). Thirteen patients received postoperative chemotherapy, including 2 patients with stage II disease.

Metanephric Adenofibroma

Another tumor with prominent stromal features that can resemble CMN is metanephric adenofibroma (Arroyo et al, 2000). The epithelial component of these tumors can range from inactive metanephric adenoma to Wilms tumor. Other lesions contain areas morphologically identical to papillary RCC. This uncommon entity may be derived from ILNR (Arroyo et al, 2000). Metanephric adenofibromas with a composite Wilms tumor component occur at a young age (mean of 12 months), similar to other ILNR-related Wilms tumors that develop in patients with DDS and aniridia. None of these tumors have recurred after nephrectomy, but all have been treated with Wilms tumor chemotherapy.

Renal Cell Carcinoma

RCC is the most common renal malignancy in the second decade of life. Only 5% of RCCs occur in children (Hartman et al, 1982; Broecker, 1991). An abdominal mass is the most common presentation, but hematuria is more common than in Wilms tumor (Broecker, 1991). Imaging studies cannot differentiate RCC from other solid renal tumors. There is a higher incidence of papillary RCC in children (Renshaw et al, 1999; Selle et al, 2006). These tumors, typically seen in adolescence or young adults, are genetically unique in that they have chromosome translocations involving a common breakpoint in the *TFE* gene located at Xp11.2 (Bruder et al, 2004). These tumors differ from adult RCC in that immunoreactivity for epithelial markers is reduced or absent.

Another type of RCC more often seen in children is renal medullary carcinoma, found in patients with sickle cell hemoglobinopathy (Swartz et al, 2002). The median age at presentation is 13 years, but the tumor can be found in much younger children. It is a highly lethal tumor.

Complete tumor resection is the most important determinant of outcome in RCC. Raney and colleagues found that all children with stage I lesions survived, and others have reported 64% to 80% survival for patients with stage I and II tumors (Dehner et al, 1970; Castellanos et al, 1974; Raney et al, 1983; Aronson et al, 1996). Partial nephrectomy has been used in pediatric patients with RCC, but outcome data are limited (Cook et al, 2006). Younger age at diagnosis is a favorable prognostic factor (Raney et al, 1983). Regional lymph node involvement does not portend the same poor prognosis as adult RCC (Geller and Dome, 2004). Geller and colleagues reported that patients with TFE+ translocation and positive nodes were found to have 93% survival at a median follow-up of 4.3 years (Geller et al, 2008). However, others have noted higher rates of relapse (Perlman, 2010). Like RCC in adults, these tumors are typically not responsive to chemotherapy or radiation therapy, although case reports of successful adjuvant treatment have been published (Chowdhury et al, 2013).

Angiomyolipoma

Renal angiomyolipoma is a hamartomatous lesion that is only rarely seen in childhood. There is a clear association with the tuberous sclerosis complex (TSC), and presentation is more often bilateral in these patients (Blute et al, 1988; Ewalt et al, 1998). The renal lesions of the TSC include angiomyolipoma, simple cysts, polycystic kidney disease, and RCC. Angiomyolipoma develops in up to 80% of patients with TSC (Ewalt et al, 1998). Renal cysts occur in up to 30% of patients with TSC. Mutations of one of two genes on chromosome 9 (*TSC1*) and chromosome 16 (*TSC2*) are found in 85% of TSC patients (Crino et al, 2006). It has been postulated that these genes act as tumor suppressor genes and that the LOH of *TSC1* or *TSC2* may explain the progressive growth pattern of renal lesions seen in these patients (Henske, 2004).

The incidence of angiomyolipoma increases with age. Ewalt and colleagues reported on 60 patients with TSC who were followed with periodic ultrasonography. The average age at which a normal ultrasound scan became abnormal was 7.2 years (Ewalt et al, 1998). Angiomyolipomas were found in 45 children. Growth of the lesion was observed in 28 children. Girls were more likely to have an increase in the size of the lesion. All patients with lesions greater than 4 cm in diameter were postpubertal. Annual ultrasound examinations are recommended after puberty. Children with growing lesions (Fig. 155-13) can be managed with embolization or partial nephrectomy before they become symptomatic with bleeding (Lee et al, 1998; Williams et al, 2006). The risk of serious bleeding appears to correlate with a diameter greater than 4 cm (Blute et al, 1988; Dickinson et al, 1998; Steiner et al, 1993). Some lesions are fat poor, and differentiation from other renal tumors—for example, RCC—on imaging studies can be difficult (Hindman et al, 2012). In some cases, biopsy of the lesion may be needed to confirm diagnosis of angiomyolipoma before proceeding with treatment. Nephron-sparing approaches are recommended in children

Figure 155-13. Angiomyolipoma of the right kidney in a patient with tuberous sclerosis.

with the TSC because of the presence of multiple, bilateral lesions and the risk of development of new lesions.

Mechanistic target of rapamycin (mTOR) inhibitors have shown promise as a new type of therapy for reducing the size of TSC-associated angiomyolipomas and represent the first systemic therapeutic approach to treat the underlying cause of TSC (i.e., targeting unregulated mTOR activation). *TSC1* or *TSC2* mutations in patients with TSC give rise to hyperactivation of the mTOR pathway. A randomized placebo-controlled trial reported that 42% of patients had at least a 50% reduction in total volume of angiomyolipoma after treatment with everolimus compared with 0% of placebo (Bissler et al, 2013). The patients were all age 18 years or older.

KEY POINTS: RENAL TUMORS

- Deletions of *WT1*, located on chromosome 11p, are found in patients with aniridia and Wilms' tumor. Mutations of *WT1* occur in DDS.
- All patients with Wilms tumor should undergo either CT or MRI of the abdomen. Routine exploration of the contralateral kidney at the time of nephrectomy is not necessary when preoperative imaging demonstrates a normal contralateral kidney.
- Screening with serial renal ultrasound examinations has been recommended in children at high risk for development of Wilms tumor. Review of most studies suggests that 3 to 4 months is the appropriate screening interval. It is recommended that screening be performed when a condition has a Wilms tumor incidence of greater than 5%.
- Local recurrence is increased in Wilms tumor patients with local tumor spillage, and this is now classified as stage III disease. The 2-year survival rate after local recurrence is 43%.
- Patients with bilateral Wilms tumor should be treated with preoperative chemotherapy. This will allow more patients to undergo renal-sparing surgery in an attempt to decrease the risk of renal failure.
- Congenital mesoblastic nephroma is the most common renal tumor in infants.
- There is a higher incidence of papillary RCC in adolescents. These tumors are genetically unique in that they have chromosome translocations involving a common breakpoint in the *TTF* gene located at Xp11.2.
- Angiomyolipoma develops in up to 80% of patients with TSC. mTOR inhibitors have shown promise as a new type of therapy for reducing the size of TSC-associated angiomyolipomas.

Treatment and Outcomes

Late Effects

Other Bladder Tumors

Female Genital Tract

Testicular Tumors

Paratesticular Rhabdomyosarcoma

Treatment strategies for patients with bladder/prostate rhabdomyosarcoma (RMS) have changed dramatically since the first Intergroup Rhabdomyosarcoma Study (IRS I; 1972-1978). Primary anterior exenteration ([Horn and Enterline, 1958](#); [Ferrer et al, 2006](#)) has been replaced by organ preservation strategies. In IRS IV (1993-1997), the bladder preservation rate among 88 analyzed patients was approximately 62%, which was significantly improved from IRS I (23%) ([Arndt et al, 2004](#)). However, a detailed evaluation of preserved bladder function is lacking, leaving the efficacy of this approach uncertain. The relative roles of surgery versus radiotherapy in local control also remain a subject of considerable debate. Simultaneously, continued advances in the molecular/genomic characterization of RMS promise improved risk stratification and new insights into molecular mechanistic drivers.

EPIDEMIOLOGY AND SYNDROMIC ASSOCIATIONS

Approximately 350 cases of RMS are diagnosed annually in the United States; of these, 15% to 20% arise from the genitourinary system ([Maurer et al, 1988](#); [Crist et al, 2001](#)). RMS is the most common soft-tissue sarcoma in children and is the third most common pediatric solid tumor, representing 5% to 15% of all childhood solid tumors. Bladder/prostate RMS demonstrates a bimodal age distribution with incidence peaking from ages 0 to 2 and again in adolescence. Boys are preferentially affected. The cause is unclear. Reports have suggested a higher risk of RMS in children with poor prenatal care or children conceived with assisted reproductive techniques, but overall, genetic factors are considered more important in pathogenesis than environmental factors ([Shrestha et al, 2013](#); [Williams et al, 2013](#)).

Most cases of RMS are considered to be sporadic; however, a genetic basis is inferred from the association of RMS with certain syndromic conditions. These include Li-Fraumeni syndrome, neurofibromatosis, basal cell nevus syndrome, Costello syndrome, Noonan syndrome, and multiple endocrine neoplasia type 2A.

Li-Fraumeni syndrome results from germline mutations of the p53 tumor suppressor gene. Patients are predisposed to sarcomas, breast cancer, brain tumors, adrenal carcinoma, and leukemia. The overall cancer risk in affected individuals may be 50% by age 30. Soft tissue sarcomas, typically seen by age 10, account for 15% to 20% of tumors in these patients ([Malkin et al, 1990](#); [Diller et al, 1995](#)). Neurofibromatosis is an autosomal dominant disorder.

Deregulation of Ras protein function predisposes patients to malignancy ([Oguzkan et al, 2006](#)). In IRS IV, the incidence of neurofibromatosis 1 among enrollees was noted to be 20 times greater than in the normal population. The lifetime risk of RMS has been estimated to be 10% among patients with neurofibromatosis 1 ([Sung et al, 2004](#)), who have a particular predilection for bladder/prostate RMS, prompting some authors to recommend surveillance ([Sung et al, 2004](#)). Basal cell nevus, or Gorlin syndrome, confers constitutive activation of the hedgehog signaling pathway as a result of defects in the *PTCH* gene ([Hahn et al, 1996](#); [Johnson et al, 1996](#)). These abnormalities cause tumor cell resistance to apoptosis ([Kappler et al, 2003](#)). This syndrome is characterized by overgrowth features, skeletal abnormalities, and benign and malignant tumors. Patients are at particular risk for basal cell carcinoma, medulloblastoma, and RMS. Noonan syndrome is distinguished by facial abnormalities, short stature, and cardiac abnormalities. Hematologic and solid tumors result from PTPN11 abnormalities affecting the Ras-mitogen-activated protein kinase signaling pathways ([Jongmans et al, 2011](#)). Costello syndrome is an autosomal dominant disorder that manifests clinically as mental retardation, unusual facial features, heart abnormalities, and short stature ([Quezada and Gripp, 2007](#)). In Costello syndrome, permanent activation of *HRAS* results in unchecked cell division ([Rauen, 2007](#)). Cancer eventually may occur in 15% of affected individuals. In one report of 200 patients, 13 (6.5%) eventually developed pelvic RMS prompting a recommendation for screening ultrasound scans every 3 to 6 months ([Gripp et al, 2002](#)). Multiple endocrine neoplasia type 2A is associated with medullary thyroid carcinoma, pheochromocytoma, and hyperparathyroidism. It is inherited in an autosomal dominant fashion and results in activating mutations of the *RET* proto-oncogene. Alveolar RMS has been reported in these patients, and some authors have recommended screening ([Jones et al, 2010](#)).

PATHOLOGY AND MOLECULAR BIOLOGY

The RMS histologic classification system was originally developed by [Horn and Enterline \(1958\)](#) and included four subtypes: embryonal, alveolar, pleomorphic, and undifferentiated. Recognition that pleomorphic tumors were anaplastic variants of embryonal RMS or alveolar RMS led to consolidation of the original system into the three histologic categories used today: embryonal, alveolar, and undifferentiated ([Kodet et al, 1993](#)). Histology alone serves as an independent prognostic indicator.

Figure 156-1. Histologic images of common rhabdomyosarcoma variants. A, Embryonal rhabdomyosarcoma (hematoxylin and eosin, $\times 200$). B, Alveolar rhabdomyosarcoma (hematoxylin and eosin, $\times 100$). (Courtesy Cheryl Coffin, Vanderbilt University Medical Center.)

Embryonal RMS is the most common form of RMS and the predominant bladder histology. Two variants of embryonal RMS account for two thirds of all genitourinary RMS: sarcoma botryoides and spindle cell. These tumors are most common in young children and have a survival rate of 85% to 90% (Ferrer and Ritchey, 2006). The botryoid variant includes polypoid tumors, often appearing as a “cluster of grapes.” They arise within a hollow viscus. Spindle cell tumors are commonly found in the paratesticular region.

Histologically, embryonal RMS resembles fetal striated muscle correlating to a gestational age of 7 to 10 weeks. Cells are spindle shaped with minimal cytoplasm, associated with larger cells harboring abundant eosinophilic cytoplasm or alternatively small, dark ovoid cells. Some cells may demonstrate characteristic cross striations (Fig. 156-1) (Horn and Enterline, 1958; Ferrer and Ritchey, 2006). Alveolar RMS is the second most common histologic type of RMS. It occurs most frequently in adolescents and young adults in the extremities and trunk. The histologic appearance correlates with striated muscle of 10 to 21 weeks’ gestational age. Small, round tumor cells form irregular nests that give the appearance of alveolar spaces (Horn and Enterline, 1958). Alveolar RMS expresses myogenin, a fetal myogenic regulatory gene, which serves as a useful immunohistochemical marker for alveolar RMS (Dias et al, 2000). Myogenin staining is absent or weak in embryonal RMS. Compared with embryonal RMS, alveolar RMS metastasizes more frequently and has a worse prognosis (Crist et al, 2001; Stevens et al, 2005). Undifferentiated tumors are the least common form of RMS and carry a poor prognosis. Histologically, they appear as primitive

round cells with scant cytoplasm and lack common antigenic markers (Dodd et al, 1989; Parham et al, 1991).

Histologic diagnosis is determined through standard immunohistochemistry and ultrastructural examination. Myogenic markers such as desmin, muscle-specific actin, myosin, and myoglobin are routinely used. As mentioned earlier, nuclear transcription factors that initiate myogenesis, MyoD and myogenin, are also being used (Cessna et al, 2001; Morotti et al, 2006; Parham and Barr, 2013).

The most significant development in more recent RMS research is the discovery of oncogenic fusion proteins produced by chromosomal translocations. Although histologic and clinical differences between embryonal RMS and alveolar RMS have long been recognized, molecular genetic analysis only more recently has been able to distinguish two distinct subtypes of alveolar RMS: fusion positive and fusion negative. Translocations between chromosomes 2;13 or 1;13 result in disruption of specific genes in 2q35 or 1p30 and 13q14. Rejoining these segments leads to the formation of fusion genes. The involved genes on chromosomes 2 and 1 are *Pax3* and *Pax7*. These genes are members of the paired box family of transcription factors (Barr et al, 1993; Davis et al, 1994). The chromosome 13 fusion partner is *FOXO1*, which encodes transcription factors from the forkhead family (Galili et al, 1993; Davis et al, 1994). The resulting fusion genes *Pax3-FOXO1* and *Pax7-FOXO1* are believed to encode proteins involved in alveolar RMS pathogenesis and confer a more aggressive phenotype (Parham and Barr, 2013). It appears that roughly 80% of alveolar RMS tumors are fusion positive.

The clinical relevance of these molecular features was highlighted in a report from the Children’s Oncology Group (COG) Soft Tissue Sarcoma Committee. In a survival analysis, patients with intermediate-risk RMS, *Pax3-FOXO1*⁺ alveolar RMS ($n = 85$), *Pax7-FOXO1*⁺ alveolar RMS ($n = 23$), and translocation-negative alveolar RMS ($n = 21$) and 305 patients with embryonal RMS were evaluated for event-free survival (EFS) and overall survival (OS). As expected, EFS and OS were worse at 5 years for patients with alveolar RMS compared with patients with embryonal RMS. *Pax3/Pax7-FOXO1* fusion-positive patients had inferior EFS compared with patients with fusion-negative alveolar RMS and embryonal RMS (Fig. 156-2). Additionally, OS was worse for patients with *Pax3* fusion compared with patients with *Pax7* fusion (Skapek et al, 2013). These findings provide insight into the 20% of patients with alveolar RMS who have outcomes more consistent with embryonal RMS, as 20% of patients with alveolar RMS are fusion negative. Future COG sarcoma studies will likely use fusion status to stratify patients into risk groups for treatment.

Studies are under way to understand the oncologic drivers downstream of these translocation proteins. Preliminary studies using genome-wide ChIP sequencing identified transcriptional targets of *Pax3-FOXO1* protein such as fibroblast growth factor receptor 4, which enhances proliferation and cell survival in alveolar RMS; insulin-like growth factor receptor 1, which is known to stimulate myoblast growth; and another growth-promoting gene, the c-Met receptor (Engert et al, 1996; Lagha et al, 2008; Cao et al, 2010; Crose et al, 2012; Keller and Guttridge, 2013; Epstein et al, 1996; Ginsberg et al, 1998). Finally, it appears that *Pax-FOXO1* fusion proteins also can disrupt the function of MyoD-regulated genes such as myogenin, p21, and muscle creatine kinase (Calhabeu et al, 2013).

KEY POINTS: PATHOLOGY AND MOLECULAR BIOLOGY

- Embryonal is the most common histology for bladder or prostate lesions.
- Alveolar histology is uncommon in the bladder or prostate; more recent studies indicated two distinct types, *PAX-FOXO1* fusion positive and negative, and fusion-positive tumors carry a worse prognosis.

Figure 156-2. Event-free survival of patients with alveolar rhabdomyosarcoma (ARMS) based on *PAX-FOXO1* fusion status compared with an embryonal RMS (ERMS) cohort. (From Skapek SX, Anderson J, Barr FG, et al. *PAX-FOXO1* fusion status drives unfavorable outcome for children with rhabdomyosarcoma: a Children’s Oncology Group report. *Pediatr Blood Cancer* 2013;60:1411–7.)

TABLE 156-1 Nodal Drainage Patterns for Genitourinary Rhabdomyosarcoma

PRIMARY TUMOR SITE	NODAL DRAINAGE
Bladder/prostate	Pelvic and retroperitoneal nodes at or below renal arteries
Uterus/cervix	Pelvic and retroperitoneal nodes at or below level of renal arteries
Paratesticular	Pelvic and retroperitoneal nodes at or below level of renal arteries (inguinal nodes if scrotal skin is involved)
Vagina	Pelvic and retroperitoneal nodes at or below level of renal arteries
Vulva	Inguinal nodes
Retroperitoneum/pelvis	Pelvic and retroperitoneal nodes
Perianal/perineal	Inguinal and pelvic nodes; may cross midline

KEY POINT: PRESENTATION

- Bladder/prostate tumors typically manifest with symptoms of obstruction, retention, or hematuria.

Evaluation

An abdominal/pelvic ultrasound scan is commonly the first study obtained in children with hematuria or obstructive symptoms. When a mass lesion is suspected, definitive imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is indicated. The site of origin—prostate versus bladder—can be difficult to ascertain. The pelvic nodal basin of bladder/prostate tumors should be assessed using fine-cut CT or MRI. CT scan of the chest is required to exclude pulmonary metastasis (the most common site). Bone scan, bone marrow biopsy, and aspirates also are indicated. Any metastatic sites must be identified for appropriate treatment selection. Growing evidence suggests a role for positron emission tomography combined with CT (PET-CT) in staging and monitoring disease response. [Tateishi and colleagues \(2009\)](#) and [Federico and colleagues \(2013\)](#) suggested that TNM stage and restaging after treatment were more accurately described by PET-CT than by conventional imaging.

Biopsy Techniques and Management of Obstruction

Biopsy for definitive diagnosis can be challenging. The limited size of pediatric resectoscopes and narrow width of hot loupes makes adequate endoscopic biopsy difficult. Circumscribing a section of a polypoid tumor using cutting current and subsequently removing the section intact with biopsy forceps can aid in obtaining an adequate sample (Snyder, personal communication, 2005). Excessive use of cautery can lead to cautery artifact, which may mimic spindle cells. Coordination with an experienced on-site pathologist is essential to evaluate frozen sections. If adequate tissue for diagnoses cannot be obtained endoscopically, COG protocols recommend open transvesical biopsy with pelvic and para-aortic lymph node sampling.

Patients may require management of lower or upper urinary tract obstruction at presentation. Early and effective management of obstruction is essential in these patients to maximize renal function, which is taxed by systemic therapy. As a general rule, I prefer placement of a urethral catheter above a suprapubic tube for bladder

PRESENTATION, INITIAL EVALUATION, MANAGEMENT, AND STAGING

Presenting Symptoms and Examination

It is estimated that 5% to 10% of all RMS occur in the bladder or the prostate. Most of these tumors are localized at presentation. Presenting symptoms commonly include urinary obstruction, urinary retention, urgency, frequency, and incontinence. Gross or microscopic hematuria occurs when the tumor breaks through the mucosal layer ([Ferrer et al, 2006](#); [Ferrer, 2010](#)). On examination, a mass corresponding with a distended bladder or tumor may be palpated. Tumors within the bladder tend to grow intraluminally and are frequently botryoid in appearance. Rarely, tumor may prolapse into the urethra and be visible externally. Tumors of prostatic origin tend to be solid masses at presentation. Patients rarely present with evidence of systemic disease. Nodal drainage is to the pelvic nodes, and they are typically not palpable ([Table 156-1](#)).

BOX 156-1 Intergroup Rhabdomyosarcoma Study Group Pretreatment TNM Clinical Staging

Stage 1: Favorable site, nonmetastatic
 Stage 2: Unfavorable site, small tumor, negative nodes, nonmetastatic
 Stage 3: Unfavorable site, larger or positive nodes, nonmetastatic
 Stage 4: Any site, metastatic

TUMOR

T1: Confined to site of origin
 ≤5 cm
 >5 cm
 T2: Fixation to surrounding tissues
 ≤5 cm
 >5 cm

SITE

Favorable: orbit, nonparameningeal head and neck sites, male (paratesticular) or female (vagina, vulva, cervix, or uterus) genital tracts
Unfavorable: all other locations (e.g., bladder and prostate)

REGIONAL LYMPH NODES

N0: Regional lymph nodes not clinically involved
 N1: Regional lymph nodes clinically involved

METASTASES

M0: No distant metastases
 M1: Metastases present

outlet obstruction. Ureteral obstruction is best managed using indwelling ureteral catheters. If these cannot be placed in a retrograde fashion, percutaneous nephrostomy tube placement with conversion to internal catheters may be considered (Meir et al, 2004).

Staging and Children's Oncology Group Risk Group Assignment

Staging patients with RMS is complex and involves the use of a TNM staging system before treatment; a surgical-pathologic group system after biopsy or resection; and risk group stratification (low, intermediate, high), which is derived from the TNM and surgical-pathologic group systems (Box 156-1, Box 156-2, and Table 156-2). The pretreatment TNM system sorts patients into favorable and unfavorable sites. Favorable sites for genitourinary RMS include paratesticular, vulvar-vaginal, and uterine tumors. Bladder/prostate tumors arise from an unfavorable site (see Box 156-1). Local stage, tumor size, histology, nodal status, and metastasis also are considered in the pretreatment stage. The surgical-pathologic group score is affected by the presence of residual disease. With the advent of organ preservation strategies, more patients undergo initial biopsy in lieu of resection, which has shifted most patients with bladder/prostate RMS from group I to group III (see Box 156-2). Patients are then stratified into low-risk, intermediate-risk, and high-risk groups. Patients with bladder/prostate RMS are commonly in the intermediate-risk group (see Table 156-2). Patient age is another independent prognostic factor, with patients younger than 1 year old and older than 10 years having inferior survival (Joshi et al, 2004; Meza et al, 2006). PAX-FOXO1 fusion status will likely be used in future studies to segregate patients into risk groups.

BOX 156-2 Postoperative Clinical Group Assignments**GROUP I**

Localized disease, completely resected

GROUP II

Grossly resected tumor with microscopic residual disease
 Regional disease with involved nodes, completely resected with no microscopic residual
 Regional disease with involved nodes, grossly resected, but with evidence of microscopic residual and/or histologic involvement of the most distal regional node (from the primary site) in the dissection

GROUP III

Incomplete resection or biopsy with gross residual mass

GROUP IV

Distant metastasis

From Scarpato KR, Ferrer FA, Rodeberg DA, et al. Genitourinary rhabdomyosarcoma in children. AUA Update Series 2013;volume 32, lesson 9.

TABLE 156-2 Rhabdomyosarcoma Risk Stratification

HISTOLOGY	CLINICAL GROUP	STAGE	AGE	RISK GROUP
Embryonal, with variants	I, II, III	1	All	Low
Embryonal, with variants	I, II	2, 3	All	Low
Embryonal, with variants	III	2, 3	All	Intermediate
Embryonal, with variants	IV	4	<10 yr	Intermediate
Embryonal, with variants	IV	4	≥10 yr	High
Alveolar	I, II, III	1, 2, 3	All	Intermediate
Alveolar	IV	4	All	High

TREATMENT AND OUTCOMES**Evolution of Multimodal Treatment**

Advances in the treatment of RMS have been facilitated by collaborative groups including the COG (encompassing the IRS), the International Society for Pediatric Oncology (SIOP), the Italian Cooperative Group (ICG), and the German sarcoma study group, Cooperativen Weichteilsarkom Studie (CWS). At the initiation of IRS I (1972-1978), treatment of bladder/prostate RMS involved radical surgery (Horn and Enterline, 1958; Ferrer et al, 2006). The combination of up-front surgery with adjuvant chemotherapy resulted in OS of 78% with significant associated morbidity related to extirpative surgical procedures (Raney et al, 1993; Ferrer and Ritchey, 2006).

After IRS I, organ preservation became a primary focus for North American and European collaborative groups. IRS II (1979-1984) and SIOP RMS 75 were the first to use neoadjuvant chemotherapy and radiation. In 10% of patients, relapse-free survival was achieved with chemotherapy alone. OS was 80%, but the functional bladder preservation rate was only 25% (Crist et al, 1995; Raney et al, 2001). In IRS III (1985-1992), with the use of doxorubicin, cisplatin, and etoposide coupled with radiotherapy, OS for bladder/prostate RMS increased to 83%, and bladder preservation rates

increased to 60% (Crist et al, 1995; Hays et al, 1995; Lobe et al, 1996; Raney et al, 2001).

In IRS IV (1993-1997), pretreatment TNM staging and a regimen of vincristine, dactinomycin, and cyclophosphamide were used. Local recurrence rates increased because radiation was limited. Arndt and colleagues (2004) reported on the IRS IV outcomes for patients with bladder/prostate RMS. At 6.1 years, EFS was 77%, and OS was 82% (Arndt et al, 2004), but only 36 (40%) of the original 88 patients were failure-free with “normal” bladder function. This study prompted increased interest in true bladder function outcomes.

IRS V was the first protocol to use risk stratification. The 3-year failure-free survival rate was 88% for low-risk, 76% for intermediate-risk and less than 30% for high-risk patients (Ferrer et al, 2006; Ferrer and Ritchey, 2006; Alexander et al, 2012).

Current Multimodel Approaches: Children's Oncology Group

Most patients with bladder/prostate tumors have tumors that are unresectable at presentation and undergo diagnostic biopsy, as opposed to an up-front primary excision that could compromise organ function. If resection is attempted as a primary procedure (e.g., a bladder dome lesion) or later in the patient's course as a secondary procedure (rare), surgeons should mark any area outside the bladder lumen suspicious for residual disease with titanium clips because frozen-section margins may be unreliable. Patients undergo imaging of the appropriate nodal drainage pathways (see Table 156-1). Pathologic confirmation of any radiographically positive nodes should be performed to avoid unnecessary radiotherapy. If a patient presents with suspicious nodes, open bladder and concomitant pelvic and para-aortic nodal biopsy may be preferred.

COG protocols advise that complete response to nonoperative therapy (chemotherapy/radiation) may not be rapid and that radical surgery should be avoided. A residual mass does not always represent viable tumor. Tumor cells may involute leaving a mass that consists primarily of stroma. They also may differentiate into mature rhabdomyoblasts that do not require radical resection (Wu and Snyder, 2004, 2009). Furthermore, residual mass does not correlate with outcome. IRS III highlighted this fact, showing that 36% of patients without radiologic response to nonoperative treatment were in complete remission based on pathologic assessment of resection specimens (Hays et al, 1995; Raney et al, 2001). On the current protocol, indications for second-look or extirpative surgical procedures are rare, and the rationale should be carefully documented and potentially discussed with COG Soft Tissue Sarcoma Committee members to ensure that the child remains on study protocols.

After diagnostic biopsy, patients proceed to the appropriate risk-stratified treatment regimen, which in the current protocol involves chemotherapy and radiation therapy. The two principal objectives of the current COG intermediate-risk study ARST0531 were to (1) compare standard vincristine, dactinomycin, and cyclophosphamide with a regimen that alternated vincristine, dactinomycin, and cyclophosphamide with vincristine and irinotecan and (2) assess the efficacy of early radiotherapy at week 4 against historical control subjects that started radiation at 10 weeks. Patients may receive a total of 42 weeks of treatment. Radiation therapy for patients with gross residual disease (group III) is 45 to 50 Gy. Final results from ARST0531 were not available at the time of this writing. Study protocols are available through the principal investigator of each participating institution and have detailed surgical guidelines.

Current Multimodel Approaches—European Cooperative Groups

The philosophical approach of SIOP to bladder/prostate RMS has varied from that of IRS and later COG. Although the latter groups

KEY POINTS: STAGING AND TREATMENT

- Organ preservation is a principal goal of treatment, and most patients treated in COG protocols undergo endoscopic/open biopsy as the initial step.
- Pretreatment TNM staging and a surgical-pathologic group classification contribute to the patient's final risk group assignment, which determines therapy.
- Bladder/prostate tumors arise from an unfavorable site, and gross residual tumor usually remains after biopsy; therefore, most patients are assigned into the intermediate-risk group.
- A residual mass after chemotherapy/radiotherapy does not mean viable tumor remains.
- Rhabdomyoblasts are differentiated tumor cells that do not require further treatment.

focused on bladder preservation, SIOP Malignant Mesenchymal Tumor (MMT) 84, MMT 89, and MMT 95 (1984-2003) (Flamant et al, 1985; Stevens et al, 2005; Oberlin et al, 2012) took a fundamentally different view on local control, avoiding radiation. Similar to COG, biopsy is usually the first intervention. Patients are treated with chemotherapy and assessed for a response. In MMT 84, standard chemotherapy included ifosfamide, vincristine, and actinomycin. Patients enrolled in MMT 89 also received ifosfamide, vincristine, and actinomycin as primary therapy. In MMT 95, patients were randomly assigned to receive either ifosfamide, vincristine, and actinomycin or a six-drug regimen consisting of ifosfamide, vincristine, actinomycin D, carboplatin, epirubicin, and etoposide. Tumor response is evaluated radiographically and by endoscopy. Patients not exhibiting a complete response are considered for conservative surgery (tumorectomy, partial cystectomy, or prostatectomy). Radiotherapy is used only in cases in which a cure is not achieved by chemotherapy and surgery. If necessary, radical surgery is considered as opposed to external-beam radiotherapy to avoid the late consequences of external-beam radiotherapy (Flamant et al, 1985; Stevens et al, 2005; Oberlin et al, 2012).

Using this approach, SIOP reported the combined results for MMT 84, MMT 89, and MMT 95 (Jenney et al, 2014). There were 175 patients eligible for analysis. Botryoid and embryonal tumors were most common with alveolar tumors comprising only 6% of the total group. Key outcomes included EFS and OS, which were 63% and 77%, respectively. Although the 5-year OS was similar to other international groups, the EFS was lower than that reported by COG. It is assumed that the lower EFS is related to the diminished use of radiotherapy in these trials. The similar OS may reflect the ability to “recover” some of these patients with second-line therapy. The percentage of preserved bladders increased from 69% to 73% and, most recently in MMT 95, to 76% (Jenney et al, 2014). Similar to SIOP protocols, the most recently reported ICG studies, ICG-79 and ICG-88, focused on up-front three-drug chemotherapy and attempted to avoid radiotherapy. EFS and OS results were not significantly different from the results observed in SIOP studies (Rodeberg et al, 2011).

Results from the CWS study, CWS-96, were reported in 2011 (Seitz et al, 2011). Patients underwent biopsy and subsequently received neoadjuvant chemotherapy with three drugs. Radiologic response after 9 weeks determined local therapy. Patients with complete response did not receive radiotherapy, patients with better than two-thirds response received 32 Gy, and patients with less than two-thirds response received 45 Gy. Primary resection was discouraged unless it would not affect bladder function. Secondary surgery was performed only if residual disease remained after radiotherapy. There were 63 patients analyzed. Radiation was given to 60.3%, 51 underwent up-front biopsy, and only 12 had primary resection. Secondary resection was performed in 45 patients. The 5-year OS for the entire group (all stages) was 76.3%. Patients who had only chemotherapy/radiotherapy had an OS of 87.5%. Patients who had chemotherapy and surgery had an OS of 84%. Patients who had chemotherapy/radiotherapy followed by tumor resection

had an OS of 87.8%. Patients who had incomplete resection with follow-up radiotherapy/chemotherapy had an OS of only 39% (Seitz et al, 2011).

All of the cooperative groups have focused on bladder preservation. OS results between the two different approaches are similar. Protocols avoiding radiotherapy appear to have lower EFS but comparable OS suggesting that children who fail can be rescued with intensified chemotherapy. Survival for bladder/prostate RMS has not changed substantially in two decades. It is likely that novel therapies or an enhanced understanding of risk stratification, perhaps based on genomic analysis, will be required before further improvement is seen (Rodeberg et al, 2011).

Treatment of Very Young Children

Because of their increased susceptibility to treatment-related morbidity, management of infants with bladder/prostate RMS is a significant challenge, and age younger than 1 year is an adverse prognostic factor (Crist et al, 2001; Joshi et al, 2004; Malempati et al, 2011). Various collaborative groups have demonstrated significantly lower failure-free survival in infants (Ferrari et al, 2003; Joshi et al, 2004; Malempati et al, 2011). Because there is no clear evidence that the biology of RMS is different in young children, it is thought that reductions in prescribed radiotherapy are responsible. Specifically, studies by Ragab and associates (1986) and Malempati and colleagues (2011) demonstrated higher local failure rates for infants treated in IRS studies. These higher local failure rates have been associated with a reduction in recommended radiation therapy (Ferrari et al, 2003; Malempati et al, 2011). Puri and colleagues (2006) evaluated 20 infants and toddlers receiving external-beam radiotherapy; 7 of 20 experienced long-term morbidity, including altered ambulation, recurrent infections, and second malignant neoplasms. Current COG protocols allow the treating institution to deviate from protocol-prescribed radiation therapy for children younger than 24 months of age. Downward dose adjustments in chemotherapy in these young children also may be contributing to poorer outcomes. The issue of appropriate therapy for very young children remains a quandary.

Timing of Surgical Reconstruction

Although bladder preservation rates have increased, some cases still require extirpative surgery. In these instances, the appropriate timing for reconstruction is a central question. Several authors have suggested that it is feasible to perform reconstruction concomitantly with cystectomy or cystoprostatectomy. Lander and colleagues (1992) described performing immediate "le bag" neobladder reconstruction on three children undergoing cystectomy for RMS. The reconstructive procedures themselves were successful, and initial frozen sections of margins were negative. However, viable tumor was present on permanent sections, mandating further chemotherapy and radiotherapy to the reconstructed pelvis (Lander et al, 1992). Similarly, Megurian and associates (1998) noted that frozen section proved unreliable in predicting residual disease. Hensle and Cheng (2000) observed that although early reconstruction is feasible, it should be considered carefully and avoided if further local therapy is a possibility. A group from Padua, Italy, published their experience with continent orthotopic reconstruction using the "VIP" bladder (Castagnetti et al, 2014). Of nine patients undergoing urethral preservation, two experienced local recurrence despite negative intraoperative frozen-section and permanent-section evaluation. Contrasting this experience is that of the Mainz group (Stein et al, 2013). These investigators preferred to perform continent reconstruction at the time of cystectomy. Of 25 patients, 11 underwent continent cutaneous diversion, and two underwent a urethral ileocecal pouch. All of these patients are reported to be continent, and none appear to have had local recurrence (Stein et al, 2013).

The difficulty in predicting local recurrence and concerns related to irradiating the recently reconstructed genitourinary tract has prompted some authors to advocate for delayed recon-

struction. Duel and associates (1996) performed initial urinary diversion followed by delayed reconstruction in patients obtaining long-term cure. They used colonic segments to create a temporary conduit, avoiding the previously irradiated ileum. These segments were later reconfigured into the cutaneous continent reconstructions. Experience with delayed orthotopic reconstruction is limited. The group from Padua, Italy, described their disappointing continence results in two patients in which this approach was attempted (Castagnetti et al, 2014). Early reconstruction is feasible; however, the inaccuracy of intraoperative margin analysis increases the likelihood of positive margins, local tumor recurrence, and further local therapy in a reconstructed pelvis.

Outcomes

Rodeberg and colleagues (2011) looked at the outcomes of patients from IRS/COG, SIOP, ICG, and CWS collectively and comparatively; the outcomes of 379 patients were evaluated. Patients 0 to 5 years old constituted 74% of the cohort; 87% were younger than age 10. Of patients, 82% were boys. Analysis of pathology revealed that 322 of 379 (85%) had localized embryonal tumors. Metastases were observed in only 7% of patients with embryonal RMS. Non-embryonal pathology (alveolar or other) was present in 30 patients (8%). The site of origin was recorded as bladder in 59%, prostate in 29%, and bladder or prostate in 12% (Rodeberg et al, 2011). Prognostic features included local tumor invasion, tumor size, and histology. When evaluating the treatment of patients with localized bladder/prostate RMS, 48% of patients enrolled in SIOP/ICG received radiotherapy versus 85% of patients enrolled in IRS/CWS.

The collective outcomes demonstrated a 5-year failure-free survival of approximately 75% for patients with localized tumors. The 5-year OS was 84%. Most failures (88%) occurred within 3 years. The location of failures was local in 60%, regional nodes with or without local disease in 9%, and distant failure with or without local disease in 25% (Rodeberg et al, 2011). Comparative outcomes analysis of collaborative group protocols revealed no statistically significant difference between the groups in failure-free survival or OS when correcting for tumor invasion and tumor size between the groups (Rodeberg et al, 2011).

The last fully reported IRS/COG results come from IRS IV. The analysis included 88 patients. The OS at 6 years was 82%, and the EFS was 77%. The bladder was retained in 55 patients, but only 36 (40%) reported normal bladder function (Arndt et al, 2004). Functional bladder evaluation was limited in this study. In 2006, an international work group reported on continence of 62 patients age 6 years or older who did not undergo cystectomy; 43 (69%) were reported to be continent, 16 had nocturnal incontinence, and 9 had diurnal incontinence. Patients undergoing partial cystectomy had a continence rate of 73%. Of the entire group, only 11 underwent a formal urodynamics study (Raney et al, 2006). The often-cited series by Yeung and colleagues (1994) reported on 11 patients undergoing a complete urodynamics evaluation after cure for pelvic RMS; in this report, only children who did not receive radiation therapy had normal bladder function. Similarly, Hays and coworkers (1995) observed that patients receiving radiation therapy were more likely to have bladder functional sequelae and that a dose effect was present, with patients receiving doses of 40 Gy or greater having more complications.

OS has remained largely unchanged for two decades in patients with bladder/prostate RMS. The true success of bladder preservation strategies is unclear because gathered data have focused on bladder retention, not function.

LATE EFFECTS

The treatment of RMS at any pelvic site is associated with potential short-term and long-term morbidity. Relative to fertility and sexual function, Raney and coworkers (2006) analyzed the urologic complications of 164 patients treated for bladder/prostate RMS from an international cohort. Data were available on only 35 (21%)

of the patients. After treatment for bladder/prostate RMS, 25 men were potent, and 2 were impotent; 16 had preserved ejaculation, and 4 had anejaculation. Two of seven women with available data had abnormal menses (Raney et al, 2006). Mansky and colleagues (2007) used a questionnaire and serum analysis to evaluate survivors of pediatric sarcoma. Of 13 female participants, 7 (47%) became pregnant; 6 remained premenopausal, whereas 7 experienced premature menopause. With regard to male fertility, only 4 of 17 men (24%) fathered children. Among men who did not father children, nine consented to semen analysis for the study. Six of these men had azoospermia, two had oligospermia, and one had a normal semen analysis; only 29% were fertile based on history or semen evaluation. All three men who received pelvic x-ray therapy were infertile (Mansky et al, 2007). Spunt and colleagues (2005) reviewed the 20-year late effects of female survivors of pelvic RMS. Delayed morbidity was found in 24 of 26 patients. Of the whole group, 77% had endocrinologic/ovarian dysfunction, and 58% experienced gynecologic dysfunction, including absence of a uterus, ovaries, or vaginal stenosis. Although large detailed studies are lacking, it is clear that significant reproductive and sexual functional consequences occur with current treatments (Armstrong et al, 2014).

Bladder function may be impaired as a result of surgery, chemotherapy, or radiation. Arndt and colleagues' 2004 review of outcomes from patients in IRS IV suggests that despite bladder preservation strategies, more than 60% of patients have some degree of bladder dysfunction (Arndt et al, 2004). Only two studies have used urodynamics, the gold standard, to evaluate treatment. Yeung and colleagues (1994) evaluated 11 children treated for pelvic sarcoma. Seven patients received external-beam radiotherapy or brachytherapy, and all of them experienced decreased bladder capacity and irritative symptoms. Soler and colleagues (2005) evaluated eight children undergoing multimodal therapy; five experienced dysuria, urgency, frequency, and diminished capacity.

An increased risk of second malignant neoplasm is associated with radiotherapy and chemotherapy. Studies of survivors of pelvic RMS suggest that they develop secondary malignant disease at six times the normal rate (Cohen et al, 2005). Mansky and coworkers (2007) reported second malignancies including osteosarcoma, Ewing sarcoma, and T-cell lymphoma in 9% of patients treated for pelvic sarcoma. Osteosarcoma, colon adenocarcinoma, and cervical squamous cell carcinoma were among the second malignancies experienced in a series of 26 survivors (Spunt et al, 2005). International cooperative groups have validated these findings (Bisogno et al, 2012). Long-term monitoring of patients with bladder/prostate RMS in specialized survivorship clinics is recommended.

OTHER BLADDER TUMORS

Transitional Cell Carcinoma

Transitional cell carcinoma (TCC) of the bladder is an uncommon lesion in children and adolescents. In a review of 10,000 cases of bladder epithelial tumors by Javadpour and Mostofi (1969), only 38 cases of TCC occurred in patients younger than 20 years old. A more recent review indicated that about 125 cases have been reported in patients younger than age 20, only 20 of which were in patients younger than 10 years old (Lerena et al, 2010). A male-to-female preponderance of 3:1 to 9:1 exists (Hoenig et al, 1996; Lerena et al, 2010). In contrast to tumors in adults, which have been associated with environmental exposures and smoking, the etiology in children is unclear. Familial history or genetic conditions have not been associated with pediatric cases (Lerena et al, 2010). Cyclophosphamide treatment and more recently chronic exposure to dantrolene have been cited as possible etiologies (Hoenig et al, 1996; Dowling et al, 2007).

The most common presenting symptom is gross hematuria, although symptoms of bladder irritation and urinary tract infection have been noted. The diagnosis is frequently delayed in children and is often made when ultrasonography detects a lesion. It

has been postulated that ultrasonography approaches 100% sensitivity and is the preferred method for surveillance (Hoenig et al, 1996; Serrano-Durba et al, 1999). Voiding cystourethrogram is less sensitive because dye density may obscure the tumor (Lerena et al, 2010). The definitive diagnosis is made by cystoscopy and biopsy. Most lesions (75%) occur in the trigone and are unifocal, although multifocal lesions have been reported (Khasidy et al, 1990; Quillin and McAlister, 1991; Hoenig et al, 1996; Serrano-Durba et al, 1999). Most lesions (80%) are superficial, low-grade lesions. A small portion of lesions are high grade. A single case of invasive disease leading to death has been reported (Paduano and Chiella, 1988; Scott et al, 1989; Hoenig et al, 1996). Pediatric TCC is best treated with transurethral resection; intravesical therapy has had no defined role.

Typically, pediatric bladder TCC does not involve the upper tracts, and no recommendations for routine upper tract surveillance exist (Vikram et al, 2009). Recurrence appears to be rare, even when higher grade lesions have been reported (Lerena et al, 2010). Periodic surveillance with ultrasonography is recommended because it is quite sensitive in this scenario, obviating the need for serial cystoscopy. I obtain an ultrasound scan every 3 months for 1 year, every 6 months for the second year, and annually thereafter. No guidance exists regarding when to discontinue evaluation.

Cancer in the Augmented Bladder

Concern that patients undergoing urinary diversion were at risk for cancer began with extended observation of patients undergoing ureterosigmoidostomy (Husmann and Spence, 1990). It was assumed that by separating urinary and fecal streams, augmentation could avoid these complications; however, reports of cancer in patients with augmented bladders raised new concerns (Gittes, 1986; Golomb et al, 1989; Nurse and Mundy, 1989; Filmer and Spencer, 1990). Recommendations for annual endoscopic screening for patients beginning 5 to 10 years after reconstruction followed. These recommendations have been critically re-evaluated recently in light of the two following observations: (1) Most reported cases come from a patient pool biased toward infectious etiologies; few data on risk in patients with augmented bladders secondary to noninfectious etiologies are available (Golomb et al, 1989; Filmer and Spencer, 1990; Kamysan et al, 2000); (2) Patients with congenital bladder abnormalities related to exstrophy complex and spina bifida have a higher basal incidence of cancer than the normal population (Beare et al, 1956; Barrington et al, 1997; Austin et al, 2007). Husmann and Rathbun (2008) studied patients with augmented bladders who were compiled within a registry using the following criteria: (1) Patients had a minimum follow-up interval of 10 years; (2) no patient ever had a form of urinary diversion in which a mixture of feces and urine had occurred; (3) patients with a history of bladder exstrophy/epispadias complex could be included only if they had undergone bladder closure within the first 2 weeks of life; and (4) only patients with bladder augmentation secondary to neurogenic bladder, exstrophy/epispadias complex, or posterior urethral valve were included. Of the patients enrolled, 7 of 153 (4.5%) developed cancer; the median time to development of a tumor was 32 years. Bacteriuria did not correlate with the development of tumor. Incidence between ileal and colonic augments was not markedly different. Two patients who received bladder augmentation for neurogenic bladder developed multifocal TCC in their native bladder, but both had prolonged tobacco exposure. Of patients who received bladder augmentation for posterior urethral valve, 12% developed adenocarcinoma of the augmented bladder. All of these patients had end-stage renal disease, had undergone transplant, and were immunosuppressed. The authors commented that patients with a smoking history after augmentation or patients with end-stage renal disease, transplantation, and immunosuppression appear to be at greatest risk (Husmann and Rathbun, 2008).

Higuchi and colleagues (2010) compared 153 patients who had undergone ileal/colonic augmentation with age-matched and disease-matched control subjects without augmentation to

determine if an increased cancer risk was present. The authors documented no statistically significant increase in bladder cancers in patients with augmentation versus subjects without augmentation (4.6% vs. 2.6%). Their data suggested that patients with neurogenic bladder have a baseline increase in cancer rates. In addition, their data supported the concept that patients with exstrophy/epispadias are also at an increased risk. An increased risk of cancer was present in immunosuppressed patients with a history of opportunistic viral infection (Higuchi et al, 2010).

Regarding surveillance, Higuchi and colleagues (2011) evaluated the utility of annual cytology and endoscopy. The authors found cytology was not helpful because of a significant false-positive rate. The authors also noted that only 4 of 250 surveillance cystoscopies revealed suspicious lesions, none of which proved cancerous. Based on the current estimated rate of malignant transformation of 1.5% to 2.8%, the authors concluded that more than 980 cystoscopies would have to be performed over a decade to diagnose one tumor. Endoscopy of the augmented bladder was recommended only when the following criteria were met: (1) Four or more symptomatic urinary tract infections occur per year; (2) a history of gross hematuria and/or urinalysis with greater than 50 red blood cells per high-power field is present; (3) chronic perineal, pelvic, or bladder pain occurs; (4) abnormal radiographic screening studies are seen; or (5) patients with colon augmentations turn 50 years old, consistent with recommendations for colonoscopy (Higuchi et al, 2011). Similarly, using Markov model analysis, Kokorowski and associates (2011) concluded that annual cytology and endoscopy were not cost-effective and questioned their effectiveness overall.

It appears that the risk of cancer after augmentation may have been overstated. Patients with bladder augmentation who are immunosuppressed after transplantation or perhaps patients with a history of tobacco use may be in a higher risk group. The efficacy of annual cystoscopy and cytology appears questionable.

Urachal Carcinoma

Urachal adenocarcinomas in children are exceedingly rare (Rankin et al, 1993). A retrospective review of medical records from the Mayo Clinic from the period 1951-2005 identified no malignancies among urachal remnants in children (Ashley et al, 2007). A mucinous carcinoma of the urachus was reported more recently; the lesion was managed by complete surgical excision (Gupta et al, 2014).

Adenocarcinoma and Squamous Cell Carcinoma

Patients with bladder exstrophy are considered to be at increased risk for adenocarcinoma. In a review of patients with augmentation, 3 of 38 (8%) developed adenocarcinoma involving the bladder and an augmented bowel segment. The site of origin could not be determined, and all patients fared poorly. These findings are consistent with prior publications suggesting an increased risk of adenocarcinoma, squamous carcinoma, or tumors of mixed cell types in patients with bladder exstrophy (Beare et al, 1956; Smeulders and Woodhouse, 2001; Sahai et al, 2004; Woodhouse et al, 2006). The belief that early closure might diminish the rate of malignancy in patients with exstrophy does not appear to have held up because all three patients with exstrophy within the series by Husmann and Rathbun (2008) had early closure. Squamous cell carcinoma also has been reported in patients with exstrophy (Patil et al, 2012). The most common scenario appears to involve tumors occurring in patients with exposed bladders. In the absence of exstrophy or schistosomiasis, squamous cell carcinoma in pediatric patients is exceedingly rare; the youngest reported patient was 16 years old with a history of bladder calculus (Sung and Koyle, 2000).

Benign Bladder Tumors

Inflammatory myofibroblastic tumor (IMT) is a locally invasive lesion that can mimic RMS in children and young adults. The

diagnosis can be made endoscopically; however, in my experience, open biopsy is commonly needed to exclude RMS. The tumor consists of spindle cells with myofibroblastic differentiation in a collagen stroma with an inflammatory cell infiltrate. Abnormalities of the anaplastic lymphoma kinase gene (*ALK*) and the rain binding protein (*RANBP2*) have been reported. IMTs with these rearrangements are termed IMT-RA and have a higher risk of local recurrence and metastasis (Li et al, 2013). Tumors without rearrangement have been treated with celecoxib with or without surgery with some success (Berger et al, 2007; Chavez and Hoffman, 2013; Li et al, 2013).

Bladder hemangiomas or venous malformations of the bladder in children typically manifest with gross hematuria and can be difficult to distinguish from malignant lesions. An association between bladder hemangiomas and Proteus syndrome (a rare hamartomatous disorder) has been documented in two patients (Lopez-Gutierrez and Jaureguizar, 2010). These lesions can be treated by partial cystectomy or laser ablation (Ashley and Figueroa, 2010; Takemoto et al, 2011; March Villalba, 2012).

Nephrogenic adenoma is a benign papillary lesion of the bladder that is associated with recurrent infections, radiation, bladder surgery including bladder augmentation, and other forms of bladder injury. It has been rarely reported in children with congenital anomalies involving the bladder (Broecker et al, 2011). Nephrogenic adenoma also has been associated with renal transplantation (Mazal et al, 2002). Histologically, tumors have a polypoid or papillary pattern consisting of layers of cuboidal cells, which frequently organize themselves into tubular patterns (Heidenreich et al, 1999). Patients may present with symptoms including hematuria, dysuria, frequency, recurrent urinary tract infection, and bladder instability. Cystoscopy and biopsy are required for diagnosis. Treatment consists of minimizing or eliminating inflammatory stimuli (antibiotic prophylaxis or improvement in voiding function). Transurethral resection and fulguration have been used effectively. Recurrence is common, and long-term follow-up is warranted. Malignant transformation is rare (Hartmann et al, 2006).

FEMALE GENITAL TRACT

Vulvar Rhabdomyosarcoma

RMS of the vulva is extremely rare—the total number of patients with vulvar sarcoma enrolled in IRS I through IRS IV was 20. The age distribution was 12 patients younger than 10 years old and 8 patients between 10 and 20 years old (Arndt et al, 2001). Compared with other female genital sites, a larger percentage of these patients have alveolar/undifferentiated histology (9 of 20; 45%). However, because these tumors are typically localized at presentation, patients have a favorable prognosis (Andrassy et al, 1995; Martelli et al, 1999). The usual presenting symptom is a labial/vulvar mass. Clinicians should be aware that tumors also can manifest as clitoral or preclitoral masses (Bond et al, 1994; Ghushie and Drugas, 2007). Treatment may include up-front excision or biopsy followed by chemotherapy and local therapy per COG protocols; brachytherapy for treatment of vulvar lesions also has been reported (Magne and Haie-Meder, 2007; Magne et al, 2008).

Vaginal Rhabdomyosarcoma

The vagina is the most common location for RMS of the female genital tract. An analysis of IRS I through IRS IV identified 151 patients with female genital tract RMS (vulva, vagina, cervix, uterine), of which 84 (54%) originated from the vagina. Most (86%) were clinical group III, and 95% had botryoid/embryonal histology. Presenting complaints included vaginal bleeding, discharge, or a protruding mass (Fig. 156-3) (Andrassy et al, 1995, 1999; Arndt et al, 2001). The management of vaginal RMS has changed dramatically since IRS I. Each iteration of protocols has demonstrated a decreased need for surgical resection (IRS I, 100%; IRS II, 70%; IRS III, 30%; IRS IV, 13%) and excellent

Figure 156-3. Mass protruding from the vaginal introitus in a young girl with vaginal rhabdomyosarcoma.

disease-free survival (Andrassy et al, 1995, 1999; Arndt et al, 2001). OS in IRS III was approximately 83% (20 of 24). Most patients today undergo up-front biopsy followed by chemotherapy with or without local control measures (Andrassy et al, 1995, 1999; Arndt et al, 2001). Between 1997 and 2008, COG conducted two consecutive low-risk RMS studies (D9602, 1997-2004; ARST0331, 2004-2008); these studies initially limited or omitted radiotherapy for vaginal tumors. The higher than expected local failure rates prompted COG investigators to recommend that radiotherapy should not be omitted. Despite these local failures, OS was excellent in this series, suggesting good response to salvage therapy (Walterhouse et al, 2011). European studies have advocated brachytherapy documenting excellent results with survival rates of 91% (Magne and Haie-Meder, 2007; Magne et al, 2008).

Cervical/Uterine Rhabdomyosarcoma

Cervical or uterine RMS is the second most common site of female genital RMS. A more recent review using the Surveillance, Epidemiology, and End Results database described 26 cases from 1973-2006 (Kirsch et al, 2014). Of 151 patients with female genitourinary sarcoma in IRS I through IRS IV, 49 had tumors of the cervix or uterine body (Arndt et al, 2001). Patients typically present with vaginal bleeding or an abdominal mass (the latter is more common with uterine body tumors). As with vaginal RMS, radical surgery has given way to organ-sparing approaches. Corpron and colleagues (1995) published the IRS III and IRS IV pilot experience, which included 14 patients 4 months to 17 years old (mean age 5.5 years old). There were 13 patients with embryonal pathology and 1 patient with an alveolar tumor. Of eight patients with group III disease, five died; four of the deaths were due to sepsis and chemotherapy-related complications. All patients with group I disease and patients with metastatic disease at presentation survived (Corpron et al, 1995). A SIOP study using organ-sparing therapy reported survival of 10 of 11 patients with cervical/uterine RMS (Martelli et al, 1999). Organ-sparing procedures, such as cervicectomy, have been applied to select patients with cervical RMS (Kayton et al, 2009).

Ovarian Tumors

Ovarian tumors represent about 1% of childhood cancers. Similar to gonadal tumors in boys, these tumors are classified histologically as germ cell tumors (GCTs), sex cord-stromal tumors, or epithelial in origin. Tumors of epithelial origin are very rare before puberty (You et al, 2005). GCTs in girls arise from the primordial germ cells of the ovary and include teratoma (mature and immature), gonadoblastomas, and yolk sac (endodermal sinus) tumors. As in boys, gonadoblastomas occur in the setting of dysgenetic gonads and rarely metastasize. Mature teratomas (dermoid cysts) are typically benign and treated by resection alone. Immature teratomas and yolk sac tumors (YSTs) can exhibit aggressive behavior and are staged and treated according to COG protocols. YSTs along with rare embryonal carcinomas and choriocarcinomas produce serum markers, which play a role in treatment and follow-up. Prognosis for these tumors is generally very good. COG protocol 9048 treated these tumors with resection and platinum-based multiagent chemotherapy and demonstrated an overall 6-year survival of 95% for stage I tumors and 93% for stage II tumors (Rogers et al, 2004). Reports of excellent outcomes for children with stage III disease are also available. More recently, observation alone for patients with stage I tumors has been studied. Although EFS was decreased, most patients were salvaged by chemotherapy on recurrence (Billmire et al, 2014). Sex cord-stromal tumors in girls include thecafibromas, Sertoli cell tumors, Leydig cell tumors, and granulosa cell tumors. These tumors are hormonally active and may manifest with precocious puberty. Their course is typically benign (Schultz et al, 2006).

KEY POINTS: FEMALE GENITAL TRACT

- The vagina is the most common female genital site for RMS, most tumors are embryonal histology, and organ-preservation strategies have resulted in excellent OS.
- Ovarian tumors constitute 1% of all childhood cancers. Ovarian tumors are histologically classified as GCTs, sex cord tumors, or epithelial tumors.

TESTICULAR TUMORS

Prepubertal testicular tumors differ markedly from testicular tumors of postpubertal patients in that benign lesions are more common, and malignant tumors have a more favorable course. Estimates suggest that testicular tumors account for roughly 1% of pediatric solid tumors, with an incidence of 0.5 to 2 per 100,000 children. Much of the information regarding these tumors comes from the Pediatric Testis Tumor Registry (PTTR), established by the Urology Section of the American Academy of Pediatrics, or from large single-center or multi-institutional series. Conflicting data regarding the most frequent pathologic variant have raised questions about enrollment bias in the PTTR. These discrepancies do not affect clinical management, allowing for clear and simple algorithms.

Epidemiology

The PTTR suggests that the most common pathologic diagnosis in children with a testicular mass is a YST, followed by teratoma (Ross et al, 2002). A large single-center series from Turkey also found that YSTs were most common (Ciftci et al, 2001), but these findings are reversed in most single-center or multi-institutional series (Metcalf et al, 2003; Shukla et al, 2004; Agarwal and Palmer, 2006). A review from four large pediatric hospitals that included 98 patients younger than 12 years old found that teratoma was present in 48% of children; YSTs, in 15%; epidermoid cyst, in 14%; juvenile granulosa cell, in 5%; Leydig cell, in 4%; Sertoli cell, in 3%; and mixed gonadal stromal, in 1%. The remaining

9% included diagnoses such as gonadoblastoma, lymphoma, cystic dysplasia, and IMT (Pohl et al, 2004). Based on this analysis, more than 74% of prepubertal testis tumors are benign in nature. This topic was reviewed in detail by Agarwal and Palmer (2006), who acknowledged the discrepancy and concluded simply that teratoma and YSTs are the most common etiology of a testicular mass. Tumor incidence peaks near age 2, and a second increase in incidence is seen in the peripubertal period (Li and Fraumeni, 1972; Haas and Schmidt, 1995; Haas et al, 1995). Tumors are more frequent in whites than in nonwhites (Walsh et al, 2008). Incidence appears to vary with geographic location. When considering all males (prepubertal and postpubertal), some authors suggest that the incidence of testicular GCTs has been rising; however, it appears that postpubertal, not prepubertal, tumors account for this increase (Reuter, 2005).

Pathogenesis and Molecular Biology

GCTs comprise a heterogeneous group of neoplasms that derive primarily from the gonads but may arise from extragonadal sites along the migration route of the primordial germ cells to the genital ridge (midline mediastinum, peritoneum, and sacrum) (Looijenga and Oosterhuis, 1999; Oosterhuis and Looijenga, 2003; Slowikowska-Hilczar et al, 2003). Testicular GCTs comprise 98% of testicular tumors and are the most common cancer in males 15 to 35 years old (Bosl and Motzer, 1997). High levels of maternal estrogens, low and high birth weights, neonatal jaundice, and disorders of sex development (DSD) have been associated with the development of GCT. Many of these factors support the concept that initiating events occur in the prenatal or perinatal period (Depue et al, 1983; Ekblom and Akre, 1998; Richiardi et al, 2002; Reuter, 2005).

The most widely accepted association with GCT is cryptorchidism, with 10% of cases linked to a history of undescended testis (Schottenfeld et al, 1980; Halme et al, 1989a, 1989b). Patients with cryptorchidism have a fourfold higher lifetime risk of developing GCT. This risk does not appear to return to baseline after orchiopexy (Schottenfeld et al, 1980; Giwercman et al, 1987; Halme et al, 1989b; Wood and Elder, 2009). Finally, as is discussed in subsequent sections, patients with DSD are known to be at risk for the development of GCT (Rutgers and Scully, 1987, 1991; Collins et al, 1993; Skakkebaek et al, 2003). Patients with hypovirilization and gonadal dysgenesis are at highest risk.

Much remains unknown regarding the molecular pathogenesis of GCT. Intratubular germ cell neoplasia (IGCN) is considered by many authors to be a precursor lesion to GCT. Two theories predominate regarding the development of IGCN. The first suggests that aberrant chromatid exchange events lead to a chromosome 12p copy number increase; this allows zygote-pachytene spermatocytes to avoid the apoptotic effects of p53 and become cancerous (Chaganti and Houldsworth, 1998, 2000). The second theory maintains that fetal gonocytes undergo abnormal cell division owing to environmental factors and give rise to IGCN. Polyploidization precedes chromosome 12p abnormalities. These cells become vulnerable to postnatal or postpubertal development of invasive cancer (Chaganti and Houldsworth, 1998; Looijenga et al, 1999; Skotheim and Lothe, 2003). Pediatric cases are mostly diploid, with the exception of YSTs, which may be nondiploid. GCTs in children have been characterized by deletions of 1p, loss of chromosome 6q, and abnormalities of chromosome 2 and 3p (Silver et al, 1994; Jenderny et al, 1996; Stock et al, 1996; Schneider et al, 2001).

The COG conducted the largest study evaluating family history of cancer and subsequent development of malignant GCT (Poynter et al, 2010). The study enrolled 278 cases and 423 controls. No association was observed between a family history of cancer and GCT in the group as a whole. The study did observe an increased risk of GCT in males when a relative was diagnosed with cancer before age 40 years (OR 2.56, 95% confidence interval 1.02 to 6.44). Poynter and colleagues (2012) evaluated several susceptibility loci that had been identified in adult GCTs in a cohort of pediatric GCT. There were 52 cases from patients age 0 to 21 years

evaluated. Most patients were female, and the tumors were predominantly teratomas and YSTs. The single nucleotide polymorphism for *SPRY4* was significantly associated with an increased risk of GCT in young boys and adolescent boys. *BAK1* was associated with gonadal tumors in both sexes. Prior studies had identified similarities in chromosomal abnormalities present in adolescent boys and men with GCTs. These included losses on chromosomes 11, 13, and 18 and gains on 7, 8, and X (Bussey et al, 1999).

Presentation, Evaluation, and Staging

Testicular tumors most commonly manifest as a painless mass. Alternatively, the lesion may be incidentally discovered by an ultrasound scan of the scrotum to rule out torsion or investigate scrotal pain. A hydrocele is present in 15% to 20% of cases. The differential diagnosis includes other intrascrotal processes such as paratesticular tumors, epididymitis, benign epididymal lesions, hernias, and hydroceles. Patients with hormonally active tumors may be referred for precocious puberty. Patients with undescended testis may present when a testicular mass predisposes to intra-abdominal torsion (Agarwal and Palmer, 2006).

Ultrasonography

Although the sensitivity of ultrasonography approaches 100% for detection, an ultrasound scan cannot reliably distinguish benign from malignant testicular lesions. Common ultrasound features of benign and malignant testicular masses are summarized in Table 156-3 and discussed subsequently.

Teratomas appear as heterogeneous complex lesions on ultrasound scan, reflective of their composition, which typically includes three germ cell layers. They may contain cystic and solid components. Bony elements appear as calcifications with shadowing. Adipose tissue appears as echogenic areas without shadowing. Epidermoid cysts represent a monolayer teratoma and have a characteristic appearance described as "onion skin" comprised of concentric rings of alternating hypoechoic and hyperechoic lesions. YSTs are typically well circumscribed and heterogeneous in appearance. These tumors may be hypervascular in appearance and may have areas of hemorrhage and necrosis. Sertoli and Leydig cell tumors are similar in appearance and commonly manifest as a well-circumscribed hypoechoic mass. Granulosa cell tumors may contain cystic and solid components. Gonadoblastomas are solid, hypoechoic lesions and, in contrast to other testicular lesions, may occur bilaterally.

Interpretation of Biomarkers in Children

Serum biomarkers play an important role in the diagnosis and management of pediatric testicular lesions. Human chorionic gonadotropin- β is rarely elevated in prepubertal tumors. α -Fetoprotein (AFP) is normally produced by the fetal yolk sac, liver, and gastrointestinal tract. Serum AFP is elevated in YSTs, and measurement of AFP levels is valuable for diagnosis, staging, and management of patients with YST. As a result of the physiologically persistent elevation of AFP in infants younger than 1 year, interpretation of AFP levels in infants undergoing evaluation for a testis mass must be performed with caution. Although the accepted half-life of AFP is 5 days, levels may be particularly high after birth, and a normal half-life may not occur for 4 months. AFP levels frequently do not come down to basal levels until 6 to 8 months of age, and in some patients elevated levels may persist until 12 months. Several features of analysis of AFP level warrant mention. In YST, AFP is elevated (>10 ng/mL) in 92% of cases. If a child older than 1 year presents with a testicular mass and an elevated AFP, it is likely the patient harbors a YST, and an organ-sparing procedure should not be considered. Conversely, a normal AFP provides considerable assurance that the mass under evaluation is benign (Ross et al, 2002). Ross and colleagues (2002) made other nuanced observations that may help clinicians: (1) In children younger than 1 year with YST, median AFP levels

TABLE 156-3 Key Clinical and Radiologic Features of Common Testicular Tumors

NEOPLASM	AGE	KEY CLINICAL FEATURES	KEY IMAGING FEATURES
INTRATESTICULAR NEOPLASMS			
Germ Cell Tumors			
Seminomatous (seminoma)	30 yr	Rare in pediatric population	Uniformly hypoechoic, hypointense on T1, hyperintense on T2
Nonseminomatous			
Yolk sac tumor (endodermal sinus tumor)	2 yr	Common pediatric testicular neoplasm, AFP elevation	Well circumscribed, heterogeneous echogenicity Hypervascular
Teratoma	<4 yr	Postpubertal more likely to be malignant	Heterogeneous secondary to cystic/solid components, calcifications, adipose tissue
Embryonal	Late teens, adulthood	Elevated AFP and β -HCG	Heterogeneous and poorly marginated
Choriocarcinoma	Late teens, adulthood	Elevated β -HCG, gynecomastia	Heterogeneous, cystic/solid components
Sex Cord–Stromal			
Sertoli cell tumor	<1 yr	\pm Gynecomastia, Carney complex, Peutz-Jeghers syndrome	Nonspecific hypoechoic solid mass LCCSCT: heavy acoustic shadowing secondary to calcification
Leydig cell tumor	3-6 yr	Secrete androgens or estrogens, precocious puberty, African-American males	Well circumscribed, hypoechoic
Granulosa cell tumor	Juvenile: <1 yr	Mixed cystic and solid mass	Hypoechoic, solid and cystic components
	Adult: middle aged		
Mixed Germ Cell/Sex Cord			
Gonadoblastoma	5-10 yr	Phenotypic females with male karyotype	Solid and hypoechoic
SECONDARY TESTICULAR NEOPLASMS			
Leukemia/lymphoma	—	Bilateral testicular enlargement; treated leukemia/lymphoma	Decreased T2 signal intensity
EXTRATESTICULAR NEOPLASMS			
Adenomatoid tumor	20-50 yr	Nonspecific painless mass	Hyperechoic, homogeneous
Papillary cystadenoma	—	von Hippel-Lindau, bilateral ~40%	Echogenic
Extratesticular lipoma	—	Fatty lesion	Hyperechoic, homogeneous, T1 hyperintense
Paratesticular rhabdomyosarcoma	2 peaks: 5 yr and 16 yr	Solid extratesticular mass with variable heterogeneity	Hemorrhage and necrosis with increased flow on Doppler

AFP, α -fetoprotein; β -HCG, human chorionic gonadotropin- β ; LCCSCT, large-cell calcifying Sertoli cell tumor.

TABLE 156-4 Children's Oncology Group Staging System for Testicular Germ Cell Tumors

STAGE	EXTENT OF DISEASE
I	Tumor is limited to testis, completely resected by high inguinal orchiectomy. No clinical, radiographic, or histologic evidence of disease beyond the testes. If scrotal orchiectomy has been performed, all margins are negative after resection of proximal cord structures to the level of the internal inguinal ring. Tumor markers are negative after appropriate half-life decline. Patients with normal or unknown tumor markers at diagnosis must have a negative ipsilateral retroperitoneal node sampling to confirm stage I disease, if radiographic studies demonstrate lymph nodes >2 cm.
II	Microscopic residual disease is present in the scrotum or high in spermatic cord (<5 cm from proximal end). Tumor markers remain elevated after appropriate half-life interval. Tumor rupture or scrotal biopsy before complete orchiectomy.
III	Retroperitoneal lymph node involvement. Lymph nodes >4 cm by CT are considered metastases. Biopsy needed to document nodal metastases in lymph nodes >2 cm and <4 cm.
IV	Distant metastatic deposits.

CT, computed tomography.

Figure 156-4. α -Fetoprotein (AFP) levels in infants with yolk sac tumor and teratoma (ng/mL). (From Ross JH. Prepubertal testicular tumors. *Urology* 2009;74:94–9.)

are higher than children with teratoma. (2) In children older than 6 months with teratoma, AFP levels rarely exceed 100 ng/mL (Fig. 156-4).

Staging

A careful physical examination is indicated with particular focus on any evidence of precocious puberty suggesting a hormonally active tumor. Disseminated disease is rare in children. After ultrasonography and serum tumor marker analysis, if concern exists that a lesion is malignant (elevated AFP), CT scan of the abdomen and retroperitoneum should be performed. The most common site of metastatic disease is the lung, which may be assessed by CT or radiography. The COG staging system is a post-surgical system based on assessment after primary orchiectomy and imaging (Table 156-4).

Tumors Associated with Disorders of Sex Development

Patients with dysgenetic testis or hypovirilization have an increased incidence of testicular tumors. Patients harboring Y chromosomal material in their karyotype are at highest risk. The noninvasive precursors of GCTs (primarily seminoma/nonseminoma and dysgerminoma/nondysgerminoma) in these patients are presumed to be carcinoma in situ and gonadoblastoma (Skakkebaek, 1972; Cools et al, 2006). Both arise from fetal germ cells. Immunohistochemistry, messenger RNA analysis, and the resem-

blance of subsequent tumors suggest a common origin for carcinoma in situ and gonadoblastoma (Gillis et al, 2007; Looijenga et al, 2007; Pleskacova et al, 2010). The pathogenesis of tumors in patients with DSD involves the transformation of immature germ cells. Several key factors in this transformation have been identified. OCT3/4, a transcription factor that has antiapoptotic functions in primordial germ cells and can be used to identify early fetal germ cells, is one such factor (Cheng et al, 2007). Another crucial element appears to be the expression of the testis-specific protein Y-encoded (TSPY) gene in the germ cells of DSD gonads (Oram et al, 2006). TSPY is the most likely candidate for the gonadoblastoma locus on the Y chromosome and defines the section of the Y chromosome that appears to confer risk for the development of GCT (Lau et al, 2009). It has been proposed that double staining for OCT3/4 and TSPY can help identify dysplastic cells early in patients with DSD (Kersemakers et al, 2005). Additionally, studies have identified that stem cell factor is a potentially useful carcinoma in situ and gonadoblastoma marker (Stoop et al, 2008). Combined analysis on biopsy specimens could help identify individuals at risk (Pleskacova et al, 2010). A consensus statement on the risk associated with various DSD diagnoses and recommended management was released in 2007 and provides guidance for counseling and management of these patients (Table 156-5) (Looijenga et al, 2007; Pleskacova et al, 2010).

Germ Cell Tumors

According to some series, teratomas are the most common testicular tumor in children and consist of variable combinations of the three primitive embryologic germ cell layers (Metcalfe et al, 2003; Pohl et al, 2004; Shukla et al, 2004). They have a characteristic ultrasound appearance that has been described earlier and do not express AFP. In contrast to lesions in men, most prepubertal lesions are benign, consisting of mature elements only (Gobel et al, 1998). The literature contains rare reports of teratomas harboring immature elements and metastasizing (Gobel et al 1998, 2006; De Backer et al, 2008). The combination of AFP measurements and characteristic ultrasound appearance can suggest to the surgeon the presence of teratoma. The preferred treatment for suspected teratomas is partial orchiectomy (see description of technique further on) (Ross and Kay, 2004; Shukla et al, 2004; Ross, 2009; Makari et al, 2010).

Epidermoid cysts are benign lesions in prepubertal boys and may account for more than 15% of prepubertal testis lesions (Pohl et al, 2004). They consist of cysts lined with keratin-producing epithelium. They demonstrate a mixed appearance (hypoechoic and hyperechoic) on ultrasound scan, and AFP levels are normal. They are managed by testis-sparing surgery. No surveillance is required after treatment (Walsh and Rushton, 2000; Ahmed et al, 2010).

TABLE 156-5 Testis Tumor Risk Associated with Specific Disorders of Sex Development and Recommended Management

YSTs have been variably reported to be the most common or second most common testicular tumor in prepubescent boys. It is the most common malignant prepubertal tumor. YSTs also have been referred to as endodermal sinus tumor or juvenile embryonal carcinoma. They are typically well-demarcated, heterogeneous masses, which may have hemorrhage or necrosis on ultrasound scan. Grossly, they are solid and gray-yellow in color. YSTs express positive stain for periodic acid–Schiff and AFP. Schiller-Duval bodies consist of a central blood vessel surrounded by two layers of tumor cells and are pathognomonic for YSTs (Fig. 156-5). AFP levels are elevated in about 90% of patients and represent a reliable marker for follow-up studies. Most prepubertal cases (>85%) are stage I at diagnosis (Grady et al, 1995; Grady, 2000). When metastases occur, YSTs often exhibit hematogenous spread to the lungs (approximately 20%), without retroperitoneal disease. For these reasons retroperitoneal lymph node dissection (RPLND) plays very little role in prepubertal YST. RPLND is used exclusively for patients with a residual retroperitoneal mass or persistently elevated AFP after chemotherapy and orchiectomy (Ahmed et al, 2010). About 20% of stage I patients experience recurrence after orchiectomy alone. After orchiectomy, stage I patients undergo a rigorous surveillance protocol that includes chest and retroperitoneal imaging and tumor marker assessment (Connolly and Gearhart, 1993). An inguinal incision should be used in all patients with a testicular mass. When a patient with a YST has undergone a trans-scrotal orchiectomy, if the pathologic margins are negative, the patient may be treated as stage I, so long as the cord is resected to the inguinal ring. If a prior trans-scrotal biopsy has been performed, the patient should undergo completion orchiectomy and is considered stage II (Rogers et al, 2004). Hemiscrotectomy is not required in these cases. If enlarged nodes are present on imaging, biopsy is

Figure 156-5. Schiller-Duval body. (From Department of Pathology, University of Pittsburgh, <<http://path.upmc.edu/cases/index.html>>.)

indicated. Patients with adenopathy and elevated AFP are treated as stage III. Treatment protocols that use multiagent chemotherapy are recommended by the North American, English, and European groups. Survival, including patients with metastasis, approaches 100% (Mann et al, 1989; Haas et al, 1999; Mann et al, 2000; Lo Curto et al, 2003; Schlatter et al, 2003).

Gonadal Stromal Tumors

Juvenile granulosa cell tumors are described to be the most common testicular tumors affecting neonates. They are easily differentiated from YSTs because they stain negatively for AFP and stain positively for markers such as inhibin α . They have been reported in patients with ambiguous genitalia (Cortez and Kaplan, 1993; Shukla et al, 2004). These lesions are benign and are treated with a testis-sparing approach.

Leydig cell tumors are hormonally active and are associated with precocious puberty. Leydig cell tumors are responsible for about 10% of all cases of precocious puberty. Other causes of precocious puberty include pituitary lesions, Leydig cell hyperplasia, large cell Sertoli cell tumors, and hyperplastic nodules in patients with congenital adrenal hyperplasia. If confusion exists, one can exclude pituitary lesions by demonstrating an increased testosterone level with age-appropriate luteinizing hormone and follicle-stimulating hormone levels. Patients with Leydig cell hyperplasia have normal urinary 17-ketosteroids. Patients with congenital adrenal hyperplasia usually present owing to poor control. Boys commonly present between the ages of 5 and 10 with virilization, although a small percentage present with gynecomastia (Cortez and Kaplan, 1993). The tumors may be small and appear as yellow-brown nodules; histologically, they contain diffuse layers of polygonal cells, and about 40% demonstrate Reinke crystals. Reinke crystals contain lipofuscin pigment and are rod-shaped, crystal-like structures 3 to 20 μm in diameter (Fig. 156-6). Their

purpose is unknown but they are unique to Leydig cell tumors. Elevated testosterone levels are commonly found; the testosterone levels may decline after resection, but the virilizing features may persist. Because of the small size of the lesions, intraoperative localization may be difficult. The lesions are managed with an organ-sparing approach; recurrence is rare (Wegner et al, 1997).

Sertoli cell tumors typically manifest at an earlier age than Leydig tumors (mean age 52 months) and have been reported in children ranging in age from 4 months to 10 years (Thomas et al, 2001). The usual presentation is a painless mass. They have been associated with endocrinologic and genetic syndromes such as Peutz-Jeghers and Carney syndromes. Of these tumors, 10% are hormonally active, and patients may present with virilization or feminization (Gabrilove et al, 1980; Thomas et al, 2001). The tumors are usually firm, well circumscribed, and tan-gray in gross appearance. They may contain areas of hemorrhage or cysts. For infants and children up to age 5, orchiectomy is usually sufficient treatment unless the tumor demonstrates the following features: large size ($>5\text{ cm}$), vascular invasion, necrosis, cellular atypia, or increased mitotic activity. Tumors possessing these features or tumors occurring in children older than age 5 warrant a full staging evaluation. Children with retroperitoneal metastasis may be candidates for RPLND, chemotherapy, and radiation. Large cell calcifying Sertoli cell tumors are a distinct entity seen in prepubertal children and adolescents; they can be managed by simple orchiectomy.

Leukemia and Lymphoma

The most common cancers with metastases to the testis are leukemia and lymphoma. Gonadal disease or relapse in the testis may occur in 20% of patients with bulky disease (Askin et al, 1981). Because of the high success rates of systemic chemotherapy and whole-body irradiation, routine biopsy of the testis is no longer required in these patients (Trigg et al, 2000). Burkitt lymphoma occasionally may manifest as a testicular lesion, and follicular lymphomas may occur primarily in the testis (Lamm and Kaplan, 1974; Finn et al, 1999).

Testicular Microlithiasis

The incidence of testicular microlithiasis in asymptomatic males age 0 to 19 years has been reported to be 2.4% (Goede et al, 2009). A concern that these lesions are harbingers of testicular cancer has prompted some authors to recommend surveillance with ultrasonography (Furness et al, 1998; Leenen and Riebel, 2002). However, more recent studies have determined that screening ultrasound scans are not required for patients without risk factors such as infertility associated with atrophic testis and microlithiasis or testis cancer and contralateral microlithiasis (Holm et al, 2003; Hoei-Hansen et al, 2005). Some more recent publications have questioned if an association between microlithiasis and GCTs exists at all in children (Volokhina et al, 2014). Routine self-examination is the current recommendation by many clinicians.

Management Algorithms

With the recognition that most of these tumors are benign, management of prepubertal testis tumors has evolved away from radical orchiectomy. This evolution began in the 1980s, facilitated by improvements in ultrasonography and the ability for frozen-section analysis to distinguish benign from malignant lesions accurately. At the present time, patients are preferentially treated with excisional biopsy and intraoperative frozen-section analysis followed by an organ-preserving procedure. The exception is when preoperative AFP or intraoperative biopsy suggests malignancy. Ross and colleagues (2002) published their recommended approach after reviewing the results from the Prepubertal Testis Tumor Registry of the Urology Section of the American Academy of Pediatrics (Fig. 156-7).

Figure 156-6. A, Leydig cell tumor demonstrating characteristic brown appearance related to abundant lipofuscin pigmentation. B, Reinke crystals. (A, Courtesy Fernando Ferrer, MD; B, from WebPathology.com, <<http://www.webpathology.com>>.)

Clinical behavior and a contemporary management algorithm for prepubertal testis tumors: a summary of the Prepubertal Testis Tumor Registry. *J Urol* 2002;168[4 Pt. 2]:1675–8.)

Testis-Sparing Surgery Technique

Patients undergoing testis-sparing surgery should be counseled regarding the potential need for radical orchiectomy. Preoperative coordination of intraoperative frozen section is required. If the tumor is not palpable, intraoperative sonography should be available.

The testicle is approached through an inguinal incision, and early vascular control of the spermatic cord is achieved with a vessel loop or Penrose drain. The gonad is delivered through the inguinal incision, and the tunica vaginalis is incised to expose the testicle. With lesions involving or immediately adjacent to the tunica albuginea, an elliptical incision beyond the tumor margins should be made in the tunica albuginea. In patients with nonpalpable lesions, I have used intraoperative sonography for localization. Ice may be applied to reduce warm ischemia time. While awaiting intraoperative frozen pathology, the tunica albuginea may be reapproximated with 5-0 running interlocked polydioxanone suture. Intraoperative considerations for testis-sparing surgery include the presence of sufficient normal parenchyma to facilitate closure of the testis. If intraoperative frozen pathology reveals malignancy, a radical orchiectomy is completed. To my knowledge, no reports document a malignant diagnosis on final pathology when intraoperative frozen pathology revealed a benign diagnosis.

PARATESTICULAR RHABDOMYOSARCOMA

Paratesticular RMS arises from the testicular tunicae, epididymis, or spermatic cord. Up to 40% of paratesticular lesions are due to RMS (Shapiro and Strother, 1992). The tumor may invade

KEY POINTS: TESTIS TUMORS

- A large percentage of prepubertal testis tumors are benign, and testicular preservation approaches are often indicated.
- Ultrasonography cannot reliably distinguish benign from malignant lesions.
- AFP is the relevant biomarker in prepubertal testis tumors, and elevated AFP is associated with YSTs.
- AFP levels must be interpreted with caution because physiologic elevation above normal values is common in children younger than 1 year of age.

locally and/or involve the scrotal wall. These tumors represent 7% to 10% of all genitourinary RMS. Peak incidence occurs between ages 1 and 5 years, and a bimodal age distribution has been reported by some authors, with peaks at less than 1 year of age and at 16 years old (Ahmed et al, 2010). In general, patients with paratesticular RMS do better than patients with tumors arising at other sites because (1) most of these tumors are stage I at diagnosis (up to 80%), in contrast to RMS in general, in which only 13% of tumors are stage I; (2) more than 90% of patients have embryonal histology; and (3) patients with more aggressive alveolar histology appear to do better than patients presenting with alveolar histology at other locations (Wiener et al, 1994, 2001; Ferrari et al, 2002; Anderson et al, 2004; Ferrari et al, 2004).

Presentation and Staging

Patients present with a unilateral, firm, painless scrotal mass. The lesion may or may not be distinct from the gonad. Ultrasonography, typically the first interrogation, reveals a hyperechoic, heterogeneous, solid mass. Evaluation of these patients involves assessment of testicular tumor markers, liver function tests, and evaluation of the chest for metastasis using CT. Complete retroperitoneal imaging using double-contrast thin-cut CT (in patients <10 years old, 5 mm; in patients >10 years old, 7 mm) up to the level of the ipsilateral hilum is essential because this is the primary lymphatic landing site, and nodes are positive in 20% of patients.

Treatment

Patients with suspected paratesticular tumors should undergo inguinal exploration with resection of the spermatic cord up to the internal inguinal ring and marking of the stump site. Biopsy should be avoided because it may lead to contamination of the operative field. In cases where biopsy is believed to be essential, isolation of the gonad and the application of an atraumatic tourniquet is required. If frozen-section biopsy is consistent with tumor, the cord should be transected above the tourniquet, and the specimen should be kept in isolation. Any unprotected spill results in upstaging. For patients referred after trans-scrotal biopsy or resection, standard recommendations have included pretreatment re-excision of the surrounding scrotal skin, although more recent data from the German and Italian cooperative groups question the necessity for this (Dall'Igna et al, 2003; Stewart et al, 2003).

The appropriate management of regional lymph nodes is essential in patients with paratesticular RMS. Patients younger than 10 years old who are considered to be in clinical group 1 (total gross resection with negative margins) that have a negative retroperitoneal CT scan do not require further surgical treatment (Wiener et al, 2001). Patients younger than 10 years old who have evidence of positive nodes on CT scan should undergo staging ipsilateral RPLND; if all tumor is removed, the patients are classified as clinical stage II. A nerve-sparing ipsilateral technique is recommended by COG protocols, and in the hands of experienced surgeons, a laparoscopic approach is acceptable (Tomaszewski et al, 2010; Cost et al, 2012). Patients who have grossly positive lymph nodes on staging CT scan can be managed by confirmatory biopsy and are considered to be stage III. As opposed to children younger than age 10, children older than age 10 should always undergo staging ipsilateral RPLND regardless of negative CT findings. Paratesticular tumors rarely involve inguinal lymph nodes. However, when scrotal involvement occurs, inguinal node sampling should be performed. These are not considered "regional nodes," and patients with positive nodes are classified as clinical group IV.

Role of Retroperitoneal Lymph Node Dissection

Original protocols, which frequently used non-nerve-sparing bilateral RPLND for patients with paratesticular RMS, resulted in significant morbidity, such as intestinal obstruction (10%), ejaculatory dysfunction (8%), and lower extremity edema (5%). The IRS III analysis of 121 patients undergoing RPLND for paratesticular RMS compared CT evaluation of lymph nodes with the pathologic results of RPLND (mostly unilateral). Of the 121 patients, 81% had CT-negative lymph node status; of these, 14% had positive nodes on pathologic examination. Patients with negative nodes had a much higher 5-year EFS (96% vs. 69%) (Wiener et al, 1994). After IRS III, strategy shifted, and patients enrolled in IRS IV did not undergo RPLND if they had negative nodes on imaging (Crist et al, 2001). Further comparison between the two studies demonstrated a stage shift in patients categorized as group I, such that 68% of IRS III patients were group I versus 82% in IRS IV. This change was reflective of the reliance of CT only for staging in IRS IV. Comparative analysis between these studies demonstrated that adoles-

cents (>10 years old) were much more likely to have retroperitoneal disease and fared worse than children younger than age 10 (Wiener et al, 2001). As a result of these findings, COG recommendations shifted back such that all children older than 10 years should undergo RPLND.

The Italian and German groups compared the accuracy of CT versus pathologic assessment of the retroperitoneum and found that only 1 of 72 patients with a negative CT scan had positive RPLND. SIOP studies MMT 84 and MMT 89 treated patients with nonmetastatic, paratesticular RMS without RPLND (Stewart et al, 2003). Of 96 patients enrolled, 25 were age 10 or older. Only one patient underwent lymphadenectomy as initial therapy. The 5-year OS was 92%, and EFS was 82%. Relapse occurred in 16 patients, 14 in the retroperitoneum. Eight patients were salvaged with second-line chemotherapy, radiation, and in some cases lymphadenectomy. Although Stewart and colleagues (2003) recognized that these 16 patients may have been understaged, they pointed out that OS was comparable to IRS. Older age and primary tumors greater than 5 cm predisposed to poor outcome. A Surveillance, Epidemiology, and End Results–based study identified 225 cases of paratesticular RMS. Among 173 patients older than 10 years old, lymph node dissection was found to improve the 5-year OS rate from 64% to 86% ($P < .01$). Conversely, patients younger than 10 years fared well regardless of lymph node dissection status; the 5-year OS rate was 100% and 97%, respectively (Dang et al, 2013).

Although some European collaborative groups have avoided RPLND, the COG recommends RPLND for all children older than 10 years in the hope to avoid failure in the retroperitoneum and the burden of second-line therapy. The utility of PET-CT for detecting nodal involvement in RMS has been reported, and it may become a useful adjunct for retroperitoneal staging (Burnette et al, 2013).

Outcomes

Before the advent of multimodal therapy, surgery alone provided for a 2-year EFS of 50% (Sutow et al, 1970). In more recent studies from the SIOP and MMT 84 and MMT 89, the overall 5-year survival was 92%, and the EFS at 5 years was 82% (Stewart et al, 2003). These studies identified age older than 10 years and a primary tumor larger than 5 cm as adverse prognostic factors. The Italian and German cooperative groups jointly reported on 216 patients who had excellent 5-year OS and EFS of 94.6% and 90.7%, respectively (Ferrari et al, 2002). Patients with metastatic disease had a 5-year survival of only 22%. Similar to SIOP, this group has also transitioned away from RPLND. In IRS III, 3-year OS was 96%, and in IRS IV, it was 92% (Crist et al, 1995, 2001).

A unique feature of paratesticular RMS is the good outcome of patients with alveolar histology (Ferrari et al, 2004; Anderson et al, 2004). Why these patients do so well is an unanswered question. Some authors have speculated that the paratesticular location lends itself to earlier diagnosis; it is unclear if PAX fusion status of these tumors may have influenced outcome.

KEY POINTS: PARATESTICULAR RHABDOMYOSARCOMA

- Paratesticular RMS arises from the testicular tunicae, epididymis, or spermatic cord.
- In general, patients with paratesticular RMS have a favorable prognosis in part as a result of the following:
 - More than 80% are stage I at presentation.
 - Greater than 90% are embryonal histology.
 - Better than expected outcomes have been reported for patients with alveolar histology.
- Exploration through an inguinal incision should always be performed in patients suspected to have paratesticular tumors.
- Tumors in children older than age 10 require staging RPLND in COG protocols because of a higher retroperitoneal failure rate.

- BISF-W. *See* Brief Index of Sexual Functioning for Women
- Bisphosphonates
 - for castration-resistant prostate cancer, 2819-2820
 - role in renal calculi management, 1221*t*, 1221*b*
- Bites, animal and human, penile, 2381
- Bladder
 - afferent pathways in
 - cannabinoids, 1656
 - in detrusor underactivity, 1810-1812, 1812*f*
 - functional properties of, 1651-1654, 1653*f*
 - modulators of, 1654-1656
 - nitric oxide in, 1654, 1655*f*
 - pelvic organ interactions with, 1656-1657, 1657*f*
 - properties of, 1650
 - purinergic signaling, 1654, 1656*f*
 - spinal cord pathways of, 1650-1651, 1652*f*, 1652*t*
 - transient receptor potential cation channels, 1654-1656
 - aging and, 1679-1680
 - anatomy of, 1631-1635, 1632*f*
 - lamina propria of, 1633-1634
 - in pediatric patients, 3121-3122
 - smooth muscle of, 1635, 1635*f*
 - stroma of, 1634
 - urothelium of, 1632-1633, 1633*f*. *See also* Urothelium, of bladder
 - vasculature of, 1633-1634, 1634*f*
 - antenatal sonographic findings of, 3173
 - capacity of, 1692
 - diminished. *See* Diminished bladder capacity
 - nocturnal, 3312
 - in pediatric patients, 3123, 3128
 - pharmacologic therapy to increase, 1836-1866
 - recognition of, 3122

Bladder (*Continued*)

- cells, receptivity in UTIs, 244-245, 246*f*
- changes, during pregnancy, 295
- closure of, for classic bladder exstrophy, 3198-3201, 3199*f*-3200*f*
- contractility of
 - bladder emptying and, 1870-1873
 - pharmacologic therapy to increase, 1836-1866
- contraction of
 - muscarinic receptors and, 1836-1837
 - normal, in voiding, 1686-1687
- decompensation, in benign prostatic hyperplasia, 2455
- defects in, in bladder exstrophy, 3189-3191, 3190*f*
- defunctionalized, lower urinary tract dysfunction and, 1792
- development of, 2836, 3173
- duplication of, 3179, 3179*f*, 3180*b*
- dynamics of, 3332
- dysfunction of, 3331
 - with posterior urethral valves, 3264-3266
- efferent pathways to, 1657-1663
 - adrenergic, 1659
 - in detrusor underactivity, 1810, 1812*f*
 - glutamate in, 1657-1658, 1659*f*
 - glycine and γ -aminobutyric acid in, 1658
 - purinergic, 1659-1660
 - reflex circuitry, 1660-1663, 1660*f*
 - serotonin in, 1658-1659
 - terminal nerve fibers, 1657
 - transmitters in, 1657-1660
- electrical stimulation of, 1914
- emptying failure of
 - absorbent products for, 2082
 - catheterization for, 1906-1907, 2077*f*
 - clean intermittent catheterization for, 1907
 - continent catheterizable channels for, 1906-1907, 2074*f*
 - continuous catheterization for, 1907
 - external collecting devices for, 2081-2082
 - intravesical pressure increases for, 2079-2081
- emptying of
 - benign prostatic hyperplasia and, 2471
 - electrical stimulation for disorders of, 1914-1916
 - failure of, 1689*b*, 1692
 - in pediatric patients, 3123
 - pharmacologic therapy to facilitate. *See* Pharmacologic therapy, to facilitate bladder emptying
 - reconstruction and, 3333
 - reflexes that promote, 1901
 - therapy to facilitate, 1691*b*
 - urodynamic studies of, 1729-1734
- estrogens and, 1673
- expansion of, at low pressures, 1755, 1755*b*
- exstrophy of, prenatal imaging of, 2910-2911, 2912*f*
- filling of. *See also* Continence
 - abnormalities of, 1688-1690, 1689*b*
 - bladder response to, 1686
 - low-pressure reservoir, 1755, 1755*b*
 - mechanics of, 1648-1649
 - outlet response to, 1686
 - pharmacologic therapy to facilitate. *See* Pharmacologic therapy, to facilitate bladder filling and urine storage
 - smooth muscles in, 1646-1648
 - therapy to facilitate, 1690*b*
 - urodynamic studies of, 1725-1729
- in genitourinary tuberculosis, 423
- glycosaminoglycan layer, 345*e6*-345*e7*, 345*e8b*

Bladder (*Continued*)

hernia of, 3180
 high-pressure, spinal cord injury with, host defense mechanisms in UTIs and, 249
 injuries of, 2385-2388
 clinical signs and symptoms of, 2386
 complications with, 2388
 diagnosis of, 2386
 etiology of, 2385-2388
 with holmium laser enucleation of prostate, 2529
 management of, 2387-2388, 2387b, 2387f-2388f, 2387.e1f
 outcomes with, 2388
 pediatric. *See* Pediatric genitourinary trauma, bladder
 radiographic imaging for, 2386-2387, 2386f-2387f
 innervation of, in pediatric patients, 3122, 3122f
 male
 circulation of, 1619f, 1621f, 1627-1628
 innervation of, 1628
 relationships with, 1616f, 1619f, 1624-1626, 1625f-1626f
 structure of, 1626, 1626f-1627f
 trigone of, 1626-1627, 1628f
 ureterovesical junction of, 1626-1627, 1628f
 mesh perforation of, in midurethral sling, 2029-2031, 2031f, 2032t, 2033b
 natural defenses of, 247-248, 248.e1
 necrosis of, with transurethral vaporization of prostate, 2517.e4
 neoplasia in, 474
 neural tube defects and, early intervention for, 3275, 3276f
 obstruction of
 prenatal imaging of, 2909-2910, 2910f, 2913
 in renal transplant candidates, 1073
 response to, 2435-2436
 RMS causing, 3584-3585
 overactive. *See* Overactive bladder
 paralytic, 1693-1694
 pediatric imaging of, ultrasonography, 2913, 2917f
 perforation of
 after augmentation cystoplasty, 3353-3354, 3354f
 in transurethral resection of bladder tumor, 2244, 2244f
 pharmacology of
 adrenergic mechanisms, 1670-1671, 1671f
 muscarinic receptors, 1667-1670, 1669t, 1670b
 sex steroids, 1673
 physical examination of, 10, 10f
 prenatal, 2874-2875, 2875f
 in prune-belly syndrome, 3236-3237, 3237f
 pudendal nerve stimulation and, 1681
 inhibitory and excitatory frequencies for, 1681
 reconstruction of. *See also* Urinary tract reconstruction
 after RMS treatment, 3587
 regeneration of, 488-489
 for augmentation cystoplasty, 3359, 3359f
 cell therapies in, 491-492
 matrices for, 489
 tissue formation for, 489-491, 490f-491f
 using cell transplantation, 489
 release of, in robotic-assisted radical cystectomy, 2271, 2273f

Bladder (*Continued*)

sensation of
 altered, filling/storage failure due to, 1688-1689
 detrusor underactivity and, 1816
 instruments for measurement of, 1800-1802, 1802t
 terminology for, 1745
 sensory input of, pharmacologic therapy to decrease, 1836-1866
 smooth muscles of, 294-295, 1640-1648. *See also* Detrusor muscle
 storage failure of, 1688-1690, 1689b, 1692
 absorbent products for, 2082
 augmentation cystoplasty for, 2070
 external collecting devices for, 2081-2082
 storage function of, 3330-3331
 electrical stimulation for disorders of, 1902-1914
 neural control of, 1754-1755
 pharmacologic therapy to facilitate, 1836-1870
 reflexes that promote, 1900-1901, 1901f
 after retropubic suspension surgery, 1933
 therapy to facilitate, 1690b
 urinary incontinence and, 1756
 urodynamic studies of, 1725-1729

CLINICAL KEY

Smarter search. Faster answers.

Smarter, Faster Search for Better Patient Care

**Unlike a conventional search engine, ClinicalKey
is specifically designed to serve doctors by providing
three core components:**

**1 Comprehensive
Content**

The most current, evidence-based answers available for every medical and surgical specialty.

**2 Trusted
Answers**

Content supplied by Elsevier, the world's leading provider of health and science information.

**3 Unrivaled Speed
to Answer**

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!

Visit **ClinicalKey.com** for more information
and subscription options.
